1 m

INTRODUCTION

A program of work on the Ford Claim at Knutsford, B.C. was completed in early October. The work consisted of soil sampling, magnetometry and geological mapping. It was carried out by a crew of two, consisting of B. D. Pearson, P.Eng., consulting geologist and Daniel Spancers, a graduate geologist who acted as Pearson's assistant. It was designed by Pearson and C. Sampson of British Newfoundland Exploration Ltd., following a joint examination of the property on June 16.

CONTROLS

A grid was established based on the Legal Corner Post which is located at the Northwest corner of the claim. Lines were run east-west using a 50 meter nylon chain with directional control provided by a Brunton compass. Stations were established at 50 meter intervals. It was attempted to hold line spacing to 100 meters, but very erratic variations in the local magnetic field made this difficult. To compensate, compass readings were made every 50 meters, and lines were tied together by chaining on the west side (OE), the east side (2000E) and near the middle (950E). The points thus established served as control points for all geological data collected, and were the sites of soil collection and magnetometer readings. These points are plotted as dots on Plates 1, 2, 3 and 4. Occasionally, points visible on airphotos were tied into the grid for future reference. Photos used were BC 7640 - 117, 157 and 158.

- 1 -

GEOCHEMISTRY

Soil sampling was carried out by Spancers who worked with a generallypoorly-developed B horizon below the root level of a thin, heavilygrazed, grass and sage-brush vegetation. The minus 80 mesh fraction was analyzed by Min-En Labs. of North Vancouver who determined copper using hot nitric acid-perchloric acid extraction and atomic absorption techniques. Results are shown on Plate 3.

Values have not been grouped by contouring. It was judged more productive, in view of the abundance of data, (in excess of 700 samples), to break the numbers down into their component populations using cumulative probability techniques, as described by Sinclair (1976). The resulting graph (Fig. 2) reveals the presence of three distinct, major homogeneous populations, and two other distinct but minor populations. The inflection points on the graph are sufficiently sharply defined to allow separation of the populations without further graphical manipulation. In other words, overlapping values are minimal, and should cause little error in the plan display. All values in the uppermost population are anomalous with respect to the other populations and should be checked on the ground to determine their source. One value (475 ppm) is anomalous even with respect to the uppermost population, and may be the more significant in that it lies at the north end of a somewhat lower-valued south-trending zone of highs. The trend is similar to that of glacial transport in the area, and may be the result of glacial smearing from a small source area close to the site where the 475 ppm value was obtained. Investigation is warranted.

- 2 -

Most of the members of the uppermost population are sited close to zones of high magnetic gradient (see later). The presence of high copper values close to concentrations of magnetite is a well-known feature of the Iron Mask batholith and its environs.

MAGNETOMETRY

Magnetometry was carried out by Pearson. The instrument employed was a Phoenix MV-1 fluxgate type, which measures the vertical component of the total magnetic field. Sensitivity is reported as ± 10 gammas on the most sensitive scale (300 gammas full scale). In practice we found it to be somewhat less, but this was unimportant in view of a magnetic relief on the property of approximately 10,000 gammas and, locally, horizontal gradients of 160 gammas per meter.

All readings were taken over loops requiring no more than three hours to complete and each loop tied into the preceding loop, thus allowing correction for diurnal changes in the magnetic field and for instrumental drift. Relative to the high magnetic relief on the property, such corrections were minor.

The magnetic data are displayed on Plate 4. As with the geochemical results, the figures have been plotted on a cumulative probability curve (Fig. 3). However, the results are less easily interpreted. Nine separate linearities have been distinguished and, for purposes of display, classed as populations. Plate 4 has been color-coded accordingly. Some of the linearities undoubtedly represent homogeneous populations, but others (for instance the intervals 2151 - 2550 and 3301 - 3600) may each represent zones of mixing of two populations.

- 3 -

Ξ COMPONENT

In view of the time required to resolve such a complex polymodal distribution, this approach has not yet been carried to completion. Interpretation of Plate 4 should be carried out with these limitations in mind.

Of possible importance is the general south-southeast trend. A similar trend is less well defined on the geochemical map. A preceding reference to glacial smearing will be recalled. The magnetic trends imply that an elongate bedrock source of high copper values is an alternative explanation.

Reference to the geologic map (Plate 2; See next section for discussion) shows that the bulk of the magnetic relief lies close to or within areas underlain by Iron Mask Gabbro. Areas underlain by Cherry Creek Rocks have little relief and a low content of magnetic minerals.

GEOLOGICAL MAPPING

Mapping was carried out by Pearson. All outcrops were tied into grid stations. In view of the sparseness of vegetation it is unlikely that any outcrops were missed. Rock types were identified by gross visual examination and examination under a 20 power hand lens. They were compared with descriptions of various suites given by Preto (1967). Results are shown on Plate 2.

The property is underlain by a central core of moderately coarsegrained amphibole-plagioclase gabbro bordered by moderately-finegrained rocks of the Cherry Creek suite, (See Preto, 1967). The gabbro trends south-southeast and noses out near the northwest corner of the Ford Claim. Outcrop areas are generally small, but

- 4 -

in most cases, where outcrops occur, pits have been sunk or trenches dug, in order to investigate rusty zones which appear to be common in the gabbro, Fracturing is common but apparently random in orientation. The magnetic survey resulted in the discovery of one outcrop within the gabbro which contained major masses of fine-grained magnetite. In spite of the intensive prospecting throughout the area, there were no signs that this outcrop (located at 1300 S, 1000 E) had been sampled or hammered on in any way. The magnetic survey showed the likelihood that other such zones exist which have not yet been investigated. The Cherry Creek rocks generally consist of fine-grained syenite, monzonite and diorite. No attempt was made to separate these varieties in the field. Gross variations noted are as follows: A slightly coarser-grained variety containing porphyroblasts of chlorite and possessing a poorly developed mineral lineation was noted at 200S, 250E. The development of orange K-spar alteration is common, but especially so at 700S, 1850E, 0 S, 50E and 250 E, and 1000 S, 250 E. Very fine grained chlorite also appears to be common at the latter locality. Epidote veining along fractures is common, most notably at 1400 S, 775 E.

Volcanic rocks of probable Nicola age are found at several points. A large outcrop occurs just east of the claim at 800 S. Regional mapping indicates that this outcrop lies close to the eastern border of the Iron Mask batholith, an interpretation strengthened by the results of the accompanying magnetic survey which shows a pronounced

- 5 -

low crossing the northeast corner of the claim, just to the north of the outcrop. Amygdaloidal volcanics are found in a small area at 1300 S, 1750 E. There is a possibility that this exposure is a largely buried glacial erratic, but a reconnaissance of ground immediately to the northwest indicates several other small outcrops of volcanic rock, lending weight to the interpretation that a small slice of volcanics lies between the gabbro and the Cherry Creek rocks in this area.

Volcanic rubble and angular boulders are also found at 800 S, 650 E, 1800 S, 1225 E and 2000 S, 2000 E. In all cases, these may be interpreted either as glacial erratics (or their fragmented remains) or as derived from small underlying slices of volcanic rock lying upon the main gabbroic mass.

CONCLUSIONS AND RECOMMENDATIONS:

The very high magnetic gradients found in several parts of the Ford Claim must be due to features very close to the surface, probably within a hundred meters. These areas should be re-surveyed with a magnetometer using a grid spacing on the order of 5 to 10 meters in order to delineate contact zones. Vertical gradient magnetometry may also be useful. Trenching could then be carried out over critical areas, and percussion drilling where necessitated by the presence of overburden.

Respectfully Submitted

Bradford D. Pearson, P.Eng.

PERSONNEL

Bradford D. Pearson is a graduate of the Massachusetts Institute of Technology (1950), has an M.A. from Boston University (1961) and has done a further year of graduate study in Economic Geology at Harvard University. He is a member of the Association of Professional Engineers of British Columbia, a Fellow of the Geological Association of Canada, and a member of the American Geophysical Union, the Geological Society of America and the C.I.M. He has had nine years of experience as a mining and exploration geologist with Canadian Exploration Ltd., Cominco Ltd., and Utah Mines Ltd., and a further six years as an independent consulting exploration geologist in Western Canada. In the course of this work he has carried out and supervised numerous geological, geochemical and geophysical surveys.

Daniel Spancers is a graduate of U.B.C. (1977) with five field seasons of experience in geological and geochemical surveying in Western Canada and Australia.
