REPORT ON AGUR-ASH PROPERTY RIDDLE CREEK, B.C.

INTRODUCTION

This report describes the results of exploration work on the AGUR-ASH property to date. This has consisted of reconnaissance geochemical surveys for uranium, a grid controlled spectrometer survey plus some geological mapping and prospecting. Work was done at intervals in the Fall of 1977 during the course of a regional exploration program covering much of the Okanagan region. Conclusions and recommendations set forth are based on the work cited above.

SUMMARY, CONCLUSIONS AND RECOMMENDATIONS

- The AGUR-ASH property is comprised of eight unsurveyed mining claims (145 units) held in the name of British Newfoundland Exploration Ltd.
- 2. The property, situated 20 kilometers west of Penticton, British Columbia, is accessible via the Apex Mountain road.
- Work on this area to date has included reconnaissance geochemical surveys for uranium, a grid controlled spectrometer survey plus some geology and prospecting.
- 4. The ASH-AGUR claims encompass a unique complex of highly radioactive trachytes and related rocks. There are four possibilities for economic uranium concentrations which are being kep in mind in its exploration:
 - a) Hydrothermal vein deposits in surrounding rock resulting from impregnation with hydrothermal fluids related to the eruptions
 - b) Concentration of uranium during later hydrothermal alterations which have affected some of these rocks
 - c) "Porphyry" uranium potential based on large volumes of radioactive rock
 - d) Secondary uranium concentrations, including subvolcanic channel deposits.
- 5. A chemical and petrographic study (staining and thin-section work) has been completed for the radioactive volcanic rocks and derived clastics. A copy of this is included. The major conclusions are as follows:
 - a) The AGUR-ASH radioactive complex involves a series of porphyritic flows and ignimbrites together with apparently co-magmatic syenites and associated tuffs, breccias and sandstones.
 - b) Later biotite-argillite alteration has mobilized uranium in some of these rocks. This alteration phase appears to be associated with vanadium enrichment.
 - c) The most radioactive rocks tend to be boxwork syenites, felted trachytes and pink crystal tuffs or grits which have been altered by late stage radioactive fluids. Uranium concentrations in excess of 100 ppm and thorium

in excess of 500 ppm have been encountered at several localities.

- d) The most radioactive units tend to occur either directly below the Tertiary volcanics or within the lowermost flows of the Yellow Lake phonolites.
- 6. Strong uranium silt anomalies on the western edge of the trachyte flows are accompanied by equally strong anomalies in other metals, notably Mo, Cu, Zn, Ni and Co. This suggests multi-metal vein or stockwork deposits may exist in that area.
- 7. Despite problems in dealing with instrumental drift in a high thorium area, the reconnaissance spectrometer survey has outlined the most radioactive lithologies and will be useful in continued mapping and prospecting.
- 8. The following approach is recommended for 1978:
 - a) Completion of grid control for the property
 - b) Careful prospecting with hand scintillometer to outline zones which are unusually radioactive for their surroundings and exposure
 - c) Detailed geochemistry along water courses and gullies
 - d) A combined mapping, radiometric and soil geochemistry study of the radioactive zone on west margin of the Tertiary lavas.

211

Respectfully s

R.R. Culbert,

GENERAL DESCRIPTIONS

Location and Access

The AGUR-ASH property is located 20 kilometers west of Penticton, B.C. The claims can be reached from Penticton by road using 4-wheel drive vehicles by passing through the Rodgers' Ranch on Riddle Creek. Geodetic coordinates are 49° 33' N, 119° 53' W. Average elevation of the claims is about 5,000 feet.

History

There is no record of uranium exploration work having been carried out in the area covered by the AGUR-ASH claims. The ASH claims, optioned from Camaplex Resources Ltd., apparently were staked purely on geological grounds, i.e. the existence of Tertiary volcanics deduced from "four-mile" government geological maps, and not from field survey data. Our own interest in this region resulted from anomalous geochemistry derived through reconnaissance surveys.

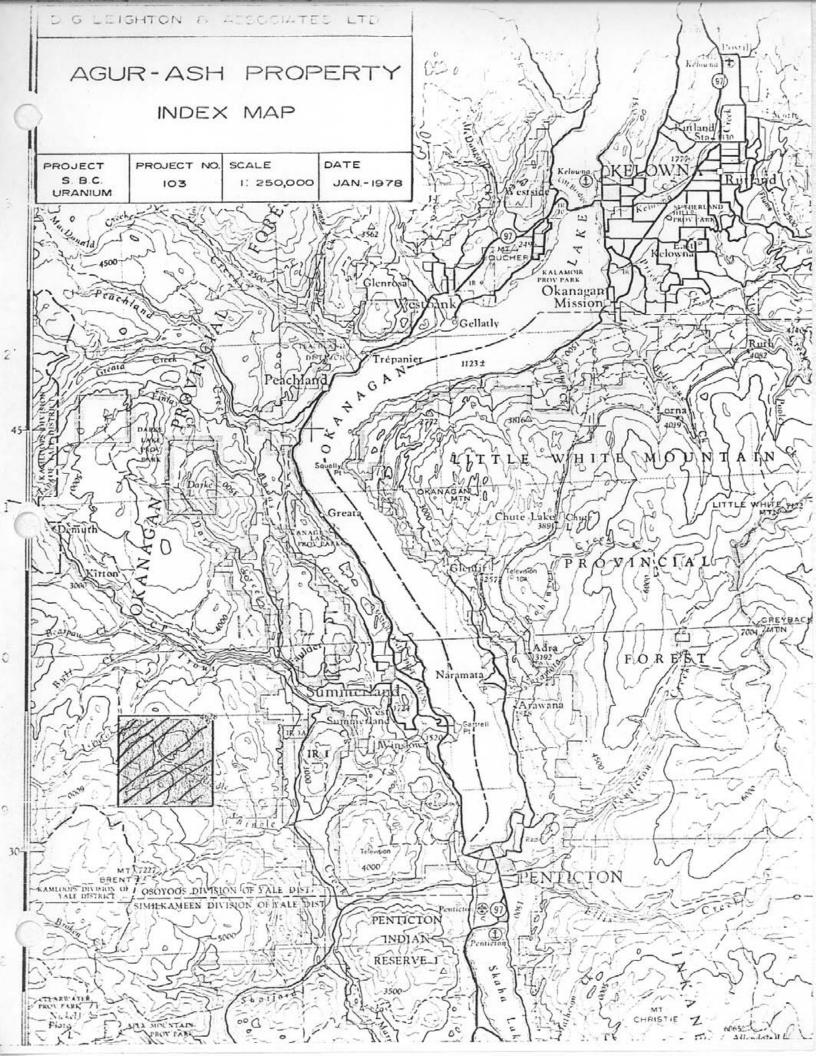

Claims

The AGUR-ASH property consists of the following mining claims held in the name of British Newfoundland Exploration Ltd.:

Property	Claims	<u>Units</u>	Record No.	Record Date	Expiry <u>Date</u>
AGUR	AGUR- I	(20)	288	26 May, 1977	26 May, 1978

GEOLOGY

Although areas of good outcrop exist on this property, bedrock exposures are rare in most parts, and the northern sector especially is overlain by glacial till and moraines. Therefore the later described sequence of radioactive volcanic flows and clastic rocks marking a rhyolite-phonolite transition near the base of Eocene Marron formation was largely derived from examination

of properties farther south. It is not clear just how well the Riddle Creek exposures conform to that regional model, but the key member of very radio-active volcanic sandstones, pink grits and ignimbrites does outcrop or form float in a few places. These rocks have a radioactivity of 800 - 1000 cps at best where encountered, and in this as well as in appearance they are very like the unit farther south. In the ASH-AGUR case, however, they are not the most radioactive rocks about.

Quartz porphyry rhyolites and tuffs of the type underlying the phonolites elsewhere have not been found in the Riddle Creek region, but a major flow of light grey dacites occurring on the northeast side of the complex may well be the local equivalents.

The major lava unit in the Riddle Creek occurrence is a type of trachyte not met elsewhere as yet, and referred to as the rectangular porphyry to differentiate it from the rhomb-porphyry phonolites of the Yellow Lake series. The feature of singular interest about the rectangular porphyries is their radioactivity, which is almost everywhere in the 500 - 700 cps range - higher than the Yellow Lake flows by a factor of 3. This exceptional radioactivity is due largely to thorium, but the rectangular porphyries tend to range 10 - 50 ppm uranium (by chemical analysis) as compared to 2 - 5 ppm for the Yellow Lake rhomb porphyries. The actual uranium contents are likely double this in both cases, as discussed under rock chemistry.

Obviously hydrothermal action following or during eruption of the rectangular porphyry would not have to concentrate the uranium greatly to produce an ore deposit. That extensive post-eruption alterations have taken place may be clearly observed in several areas where their effects vary from yellow and orange matrix staining to almost complete kaolinization of the rock.

The most radioactive lithology so far discovered in this area is a strange, light grey rock with a somewhat "felted" texture. This has been found at widely scattered locations, near the lower boundary of the rectangular porphyries. Although its relationship to other lithologies appears somewhat contradictory from one location to another, it most likely occurs as dykes.

The best exposure of the felted radioactive material is an outcrop of about 15 feet width in the north fork of Riddle Creek. Radioactivity is to 2000 cps, and no other rocks outcrop in this vicinity. The zone may be traced with scintillometers below overburden for several hundred feet, and appears to be near vertical, crossing the valley on an east-west trend. Geochemical analysis of this outcrop gave 91 ppm uranium and 360 ppm thorium. A more radioactive (to 2200 cps), but poorly exposed, occurrence of this rock has been encountered at 1350 \$ / 2000 W on the grid. A weathered sample of float from a small pit here gave an incredible 510 ppm thorium, but only 50 ppm uranium. This latter site is likely part of a fairly continuous zone of highly radioactive rocks that follows the western edge of the rectangular porphyry.

That "western edge" is a thoroughly interesting location. Besides some major geochemical anomalies and the "felted" rock radioactive zones, the basement here is of coarse Tertiary syenites. These occur in a variety of forms and phases, but are moderately radioactive (200 - 400 cps) and porphyritic. They are very likely comagnatic with at least part of the Tertiary

phonolites. To the east, the Tertiary appears to overlie regional granodiorites directly, and these outcrop again to west of the syenites. Their radioactivity of 50 - 90 cps is typical of granodiorite.

RADIOMETRIC SURVEY

In view of the role of radioactive lithologies on AGUR-ASH property, a ground radiometric survey was planned in conjunction with the laying out and flagging of a control grid. This work was contracted out to a geophysical consulting company (Nielson Geophysics Ltd.), who carried it out during July and early August. The results have been a major disappointment. A check of their work part way through the program indicated that the energy level "windows" on their spectrometer, a McPhar Spectra 44, had been slipping. Some of the lines were redone, but results suggest that this problem continued, and the final third of these results were never submitted to us because of "instrument problems". In October part of the remaining survey work was completed by ourselves using a different instrument, and some of the previous grid lines checked as well. Although the readings for each channel could be normalized between the two instruments, their characteristics were different and interchannel ratios are not comparable.

Interpretation of radiometric results on the AGUR-ASH property presents some unusual problems because of the high thorium background, the major radio-active lithologies and an apparent "magmatic" correlation between uranium and thorium.

There is an exceptionally strong correlation between readings on the uranium and thorium channels. This may be broken down for clarity into four main sources of co-variation:

i) Thorium 'scattering'

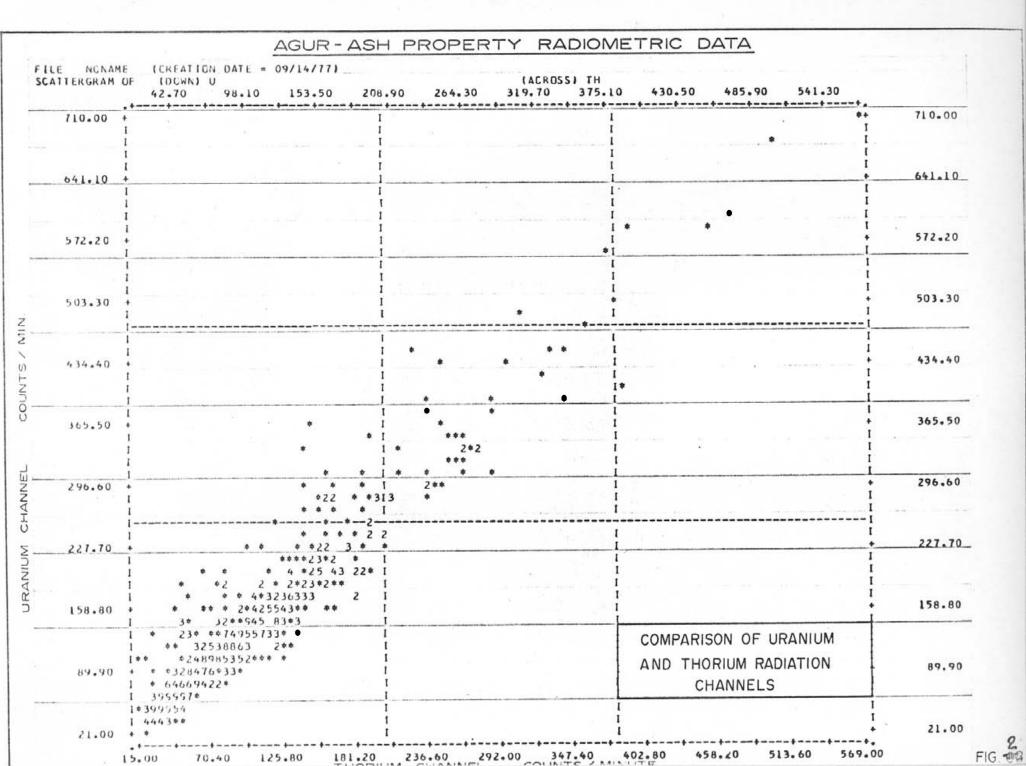

The uranium radiation channel is directly influenced by thorium radiation. This may be corrected to obtain the counts expected on the uranium channel were no thorium present, and the result is termed "stripped uranium". It is in this correction, however, that problems arise if the energy level windows of the channels are not set properly, especially when (as here) the thorium correction is large.

ii) Geometry

Both uranium and thorium counts increase in enclosed areas such as gullies and decrease in open areas such as ridges.

iii) Overburden

Overburden is considerably less radioactive than the rocks in this area, especially where this is transported till rather than residual soils. (Most of the property is blanketed by till.) The usual solution to geometry and overburden problems is to use the ratio of (stripped) uranium counts to those of thorium, thus using thorium as a measure of background radia-

tion. This has some drawbacks, including the statistical ones inherent in ratios and the ease with which uranium is leached from soil in comparison to thorium. On AGUR-ASH property, however, there is a further complication as follows:

iv) Magmatic co-variance

Except for especially high thorium in some of the "felted" rocks, the ratio of uranium to thorium in the radioactive suite on this property does not change much with the overall radioactivity of the rock. A Th/U geochemical ratio of eight is common throughout. This is presumably a reflection of magmatic partitioning.

The resulting overall correlation between readings in the uranium and thorium channels (summer data) is given in Figure 2. In looking for places where uranium may have been specifically concentrated by hydrothermal mobilization (to which thorium is less susceptible), one method is to remove the effect of all forms of thorium co-variance by simple regression. This is like saying how much more (or less) uranium radiation is found at each point than is expected from thorium radioactivity there - given all of the relationships existing between these two. Another approach is to take the ratio of stripped uranium counts to stripped potassium counts, thus using potassium as a background indicator instead of thorium. The computer has produced and plotted these two ratios, but the problems of slipping windows are apparent, and the two different surveys are not comparable. That information (Table 1) is hence being held for detailed work as mapping progresses, and only the stripped uranium data and its ratio to thorium are presented (Figure 3).

In summary, it should be recalled that this was an almost reconnaissance scale radiometric survey, with 100 meter stations on lines 150 meters apart. It fulfilled most of the objectives of such a survey, in that it will assist in mapping radioactive lithologies in areas of poor outcrop, and gives some indication of where these lithologies are overlain by thick till. limitations of such a survey are clearly demonstrated in that it entirely missed the aforementioned radioactive zone of felted rock crossing Riddle Creek's north fork, as well as some other radioactive localities known on the western rim of the lavas. There are some unexpectedly high readings or ratios in the data which will require examination next year, and more detailed mapping may well demonstrate that it responded to the areas of alteration in the rectangular porphyry. Experience, however, has now shown that the most useful radiometric method on this property is careful and systematic prospecting with hand held scintillometers, searching for relatively small zones where radioactivity is high with respect to its surroundings.

GEOCHEMISTRY

a) Rock Geochemistry

There is a strong possibility that the Riddle Creek volcanics set some sort

of record for radioactivity in extrusive rocks. According to a recent compilation by Kishimari et al, the most uraniferous flows on record are from Italy, where a unique trachyphonolite suite averages 45 ppm uranium and 210 ppm thorium. (Bostonite dykes in eastern Egypt and Colorado have been reported as containing as much as 100 ppm uranium.) The exact uranium and thorium content of the Riddle Creek complex is not yet well known. Wetchemical analyses with nitric-perchloric acid digestion has given results as high as 90 ppm for uranium and 500 ppm for thorium. Eleven samples of the radioactive volcanics which have been run by both wet-chemical and neutronactivation analysis, however, averaged $2\frac{1}{2}$ times more uranium on the neutron techniques. Likely this is a result of uranium (and presumably thorium) being locked into refractory minerals, abundant apatite being the principal suspect. There is also some possibility, however, of thorium interfering with neutron-activation analysis for uranium.

Based on the results from low energy gamma spectrometry, the average from 14 samples of rectangular porphyry flows (those not hydrothermally leached) was 50 ppm uranium and 224 ppm. The felted trachytes (8 samples) averaged 131 ppm uranium and 307 ppm thorium.

b) Soil Geochemistry

To determine the usefulness of grid-wise soil sampling in this area, two lines across the property were sampled at 50 m. intervals, and a line of soil samples was also taken from a fairly steep bank across the radioactive zone on the north fork of Riddle Creek. The former set was analyzed by neutron activation. Results have been disappointing. Uranium values have responded only very locally to the radioactive zones, and weakly in comparison to the transported anomalies of wet, organic areas. These zones are better seen by soil thorium, but it is doubtful that this would add much information to results obtained by prospecting with hand scintillometers. It is true that the uranium-thorium radioactive zones may not be the most interesting targets, but in view of the glacial overburden covering most of this property and the known accumulation anomalies, general grid soil sampling is not recommended.

c) Creek and Gully Geochemistry

Although abundant calcite is available from amydules on this property, uranium water anomalies have not been encountered. If carbonate waters are indeed involved, they do not appear to be leaching major amounts of uranium. Laboratory tests indicate that these rocks are not very susceptible to leaching by carbonate solutions in any case. It is of interest, however, that one spring of radioactive water (radon) was encountered, together with a 100 ppm uranium silt anomaly to south of the volcanic cover.

Silt and gully soil anomalies have been found in several parts of this property, those associated with the radioactive zone on western rim of the flows giving results as high as 600 ppm (confirmed by neutron activation). The highest values are in boggy, organic areas, and are hence likely trans-

ported accumulations. At one site here, however, a small set of soil samples taken across the wet lineament had the highest uranium values in a dry side-flank sample. This is one area where detailed soil sampling is recommended, along with gully soil or sediment collection on all parts of the property. Certain localities have also been noted where there is strong radioactivity over soil in which neither uranium nor thorium is sufficiently rich to explain the observation. Hand-trenching is planned in these locations, followed by radon gas measurements if a radiation source is not uncovered.

A composite of silt samples from the southwest part of the volcanic margin was found to contain, in addition to 355 ppm uranium, anomalies of 90 ppm Mo, 590 ppm Cu, 505 ppm Ni, 122 ppm Co and 1850 ppm Mu. This multi-element anomaly suggests that uranium may be present as multi-metal vein or stockwork systems, as none of them are particularly concentrated in the flows.

The outcrop of felted rock on north fork of Riddle Creek is actually cut by that creek. There is little opportunity for "bog" accumulations here, however, and two samples taken below this have very little uranium in analyses by the usual wet chemical method.

GENERAL

Radioactive flows, tuffs and related volcanic sediments have been discovered in three areas of Tertiary igneous activity northwest of Penticton. From the northwest, these are the Riddle Creek area (Agur-Ash property), the Clark property at Farleigh Creek and part of the Indian Reserve between Skaha and Shingle Creek immediately west of Penticton. The three localities form an axis which includes the Corynell Tertiary syenite body at Allendale Lake, if projected to the southeast.

The Riddle Creek assemblage involves a large, radioactive trachyte flow with apparently co-magmatic syenite, derived tuffs and clastic volcanic sediments. At the other two locations, intense radioactivity is mainly associated with a pink-coloured deposit of volcanic grit, conglomerates and sandstones, together with coarse tuffs. The unit is likely a channel deposit lying beneath or within the earliest phases of the Yellow Lake phonolite eruptives.

In a regional sense, the Yellow Lake phonolites are the basal member of a major series of alkaline Eocene extrusives known as the Marron Formation. Most flows of this phonolite exhibit large rhombohedral phenocrysts of anorthoclase, and are referred to as "rhomb porphyries". This lithology is mildly radioactive, primarily due to thorium. Its petrology and chemistry has been described in detail by Dr. Neil Church of the B.C. Ministry of Mines (Geology of the White Lake Basin, Bull. No. 61, B.C. Dept. of Mines and Petroleum Resources, 1973) and will not be discussed here.

Over much of its range, the Marron Volcanics are underlain by a coarse, cemented basal conglomerate called the Springbrook Formation. In the areas of the radioactive channel deposit, however, there is a major accumulation of light-coloured pyroclastic deposits, explosion breccias, ashflows and tuffs which lie between the Marron and the Springbrook. These appear to be of rhyolitic composition, and it is at or near this abrupt rhyolite-phonolite transition that radioactive units occur.

Radioactive extrusive rocks are very rare. The purpose of this study has been to examine closely the chemistry and petrology of those in the Penticton area to determine if they have other unusual characteristics which might assist in determining the source of the radioactive elements or evaluating the economic importance of occurrences. Information was also compiled to assist in the mapping and prospecting of the properties in 1978.

The thin-section studies for this report were carried out largely by Dr. K. Lu and Prof. H. Shimazaki.

RIDDLE CREEK AREA (Agur and Ash Claims)

This large complex of radioactive volcanic rocks suffers from extensive overburden and is as yet poorly explored. From what mapping has been done, however, it appears to be the richest of the occurrences in both uranium and thorium, and the major rock types are as follows:

(a) Syenites

The lavas rest on basal tuffs or on granodiorite and quartz monzonite country rocks, except along their western boundary they are in contact with what appears to be co-magmatic syenites. This contact is one of the most radioactive zones, and the area of highest uranium geochemistry. Three different types of syenite have been observed, and these will be

referred to as the "granular", "porphyritic" and "boxwork" varieties. The first is an ordinary coarse white syenite with low mafic content. It weathers easily to a granular texture. The porphyritic style appears to have transitional phases to the "rectangular porphyry" trachyte flows. It exhibits large apatite rods in hand specimens, as well as anorthoclase phenocrysts which may take on a directive or "herring-swarm" texture. The boxwork syenites are striking rocks, and the most radioactive. They are mainly comprised of tabular anorthoclase crystals twined into a 3-directional lattice with many tetragonal voids. Transitional phases between this and the "felted trachytes" are readily observed.

In thin section, the porphyritic syenite shows zircons and small sphene crystals as well as apatite. Up to 10% of both biotite and titanaugite may be present. The phenocrysts are anorthoclase, but typically have albite rims. and staining of several specimens have shown that in some cases the replacement of phenocrysts by albite is almost complete. It also indicated that the apatite content is extremely variable, and may comprise as much as 5% of the rock. A separation of this mineral was made by the Dept. of Mines, and it was found to not represent the source of radioactivity. Some quartz is visible in thin section, but less than 2%. Multi-element analysis of one specimen showed that its composition correlated more closely with the rectangular porphyry flows (and with the ignimbrite deposit) than with the other syenites. There is also a strong visible resemblance to the Allendale syenite body located southeast of Penticton.

The boxwork syenites were studied in some detail, in part because of their striking appearance, and in part because of their radioactivity and apparent relation to the felted trachytes. The large laths which give this rock its graphic or boxwork texture are anorthoclase, and again there is a variable degree of albitization. Argite crystals have been converted to chlorite-quartz intergrowths in most cases. Sphene, fluorite and opaques are the main accessory minerals, with opaques running as high as 5%. Biotite (5 - 10%) is the major mafic mineral, and remains fresh despite strong argillic alteration in some samples.

Gradational variation between the boxwork syenite and certain felted texture rocks may be seen, at least in the southwestern contact region, where both rocks occur together and where the felted trachytes prove to be holocrystalline in thin section. Felted rocks from elsewhere on the property prove to be comprised largely of microlites, however, and their relationship to the syenites is less clear. Samples of all of these rocks share certain chemical similarities, of which the most important is their high thorium and uranium contents. Enrichment in lead, zinc and fluorite is also clear.

The uranium content of the felted series is quite variable. In comparison to the other radioactive lithologies, they generally have higher portions of acid exchangeable uranium and a greater tendency toward disequilibrium between uranium and its daughter products. These observations suggest that the radioactive elements are present in a less refactory mode in this lithology, and thin section work has shown that the most radioactive specimens have, in fact, been subject to the late-stage hydrothermal alteration.

Alteration products are variable, but include greed horn-blende, fluorite, quartz, opaques and zoisite. In one case this takes the form of veining. There may be allanite associated with the zoisite, but the radioactive component is likely dominantly with the opaque minerals.

It appears that the boxwork syenite was originally cooled as silica saturated argite syenite, and in the murky nomenclature of alkaline rocks might be termed a "larvikite". Late stage biotite formation and widespread alteration of the titan augites has changed the nature of most of the lithology.

(b) Rectangular Porphyry Trachytes

The term "rectangular porphyry" was adopted by Dr. Neil Church in 1977 to differentiate these flows from the less radio-active rhombic porphyry phonolites which occur to the south. A series of flows appears to be involved, some highly vessicular and all of a light grey colour.

The rectangular porphyry has a silica content in the 55 - 60%, while the felted rocks and boxwork syenites lie in the 60 - 65% range, and those rhombic porphyry phonolites analysed had less than 55%. On these grounds the rectangular porphyries and felted series are referred to as trachytes.

Thin sections and potassium staining indicate that the large feldspar phenocrysts are anorthoclase in various stages of albitization. As with the Yellow Lake phonolites, the fresher rocks tend to have well-formed augite crystals, but in most areas these have been altered to some combination of biotite, chlorite, zoisite, and quartz. Fresh biotite is common, although patchy, and minor carbonate alteration also occurs in some areas. Apatite and opaques are the main accessories, although sphene and small xenotine are also observed. Nephaline phenocrysts occur in some specimens.

The texture of these flows varies considerably, some showing no orientation in the microlites (unusual for flows) and others being extremely vuggy or amydoidal. Vesicule fillings include quartz, carbonate and naturolite.

The rectangular porphyry appears to have an average uranium content in the 30 - 35 ppm range, and a thorium average somewhat less than 200 ppm. This is much lower than the radioactive elements in the "felted" rock series, but the uranium content is an order of magnitude greater than encountered in the typical Yellow Lake "rhomb porphyry" phonolites. There were no other really striking chemical peculiarities observed in the rectangular porphyry series.

(c) Trachyte Alterations

The typical altered trachyte is mottled reddish-brown and yellow in hand specimen, with amber-coloured secondary biotite. This type is quite widespread, especially in the southern part of the volcanic area. Also observed are chalky rocks which have been thoroughly kaolinized, and vuggy breccias comprised of little more than the silica skeletons in which virtually all other elements appear to have been leached or replaced. Apparent brecciation is common in the altered rocks, which have not been observed yet in outcrop - presumably due to their low resistance to weathering.

In thin section, these rocks show varying degrees of silicification, argillic alteration and biotitization. Hematite and some pyrite are also observed. It appears likely that the style of alteration will vary from site to site, as will the extent to which the radioactive elements have been affected. Some of the alteration zones have patchy areas of unusually high radioactivity, the cause of which has not been determined.

One sample of the brown and yellow biotitized rock was included in multi-element analysis, and found to contain an interesting assemblage of trace elements. This included high levels of Mo, Cr, Mg, Ti and V. The vanadium was given

at 1000 ppm, which is almost two orders of magnitude above background, and this may be of direct importance in view of that element's ability to precipitate uranium from solution under a wide variety of conditions. Uranium occurs in conjunction with vanadium in most of the sandstone deposits, and apparently also at the new Blizzard subvolcanic showing. The fact that both elements are involved in late-stage hydrothermal alterations provides another possibility for the localization of uranium.

Most of the tuff or volcanic grit deposits have been altered to some extent, but those (poorly) exposed below the rectangular porphyry trachyte on lower Riddle Creek are so intensely altered that they fit better into this classification. A sample studied in thin section had originally been a lapilli tuff, but most fragments are almost entirely replaced by limonite and clay minerals. Surprisingly, a few crystals of biotite, potassium feldspar and even augite survived in fresh condition, and some of the biotite may well be a secondary hydrothermal phase. Staining of samples indicates that the rocks are potassic in a patchy fashion, again pointing to hydrothermal alteration. A very peculiar blue-green rock was found in this area, and proved to be a pumice altered by an assortment of unidentified zeolites and an unusual blue-green stain. Similar rocks were observed on the Clark property, which may be of lapidary interest.

(d) Tuffs, Grits, Conglomerates and Ignimbrites This varied and unusual unit appears in part at least to underlie stratigraphically the rectangular porphyry flows, but the best exposures lie beside the lavas and they may represent more than one horizon. They vary from classic ignimbrites and chaotic "vent facies" breccias (with

obsidian clasts) to obviously water-laid grits and conglomerates. The distinctive pink crystal grits which form the radioactive channels farther south are also encountered in this sequence. In the few places where bedding is visible, it is flat lying.

The clastic rocks are mainly located east and north of the main volcanic sequence, and are poorly exposed. One sample of classic ignimbrite was observed in thin section. This was directly associated with the pink crystal tuffs or grits, which suggests that the radioactive rocks of ignimbritic appearance with a similar association on the Skaha Indian Reserve may indeed be ashflows. (This could not be demonstrated in thin sections from that area.) Chemically, the Riddle Creek ignimbrite is similar to the trachytes, although it lacksvisible augite. It also has a fairly strong chemical correlation coefficient with the apparent ignimbrite at the reservation.

Most of the clastic rocks in the Riddle Creek area are lapilli or crystal tuffs which were at least in part waterlaid. Clasts of trachyte, syenite, devitrified glass, granite, diorite and even previous tuff units are observed in thin section. Some are fairly porous, and others completely sealed with a crystalline matrix of apparent hydrothermal origin. Analcite pockets were observed in one specimen. In view of the unit's relatively high radioactivity and of the appearance of trachytes as clasts, it seems likely that it, in part at least, represents pyroclastics accompanying eruption of the trachytes. The striking pink crystals which distinguish the radioactive grits at all three areas remain somewhat of an enigma. In composition they are K-feldspars in various stages of alteration to albite or carbonates. The colouring is likely due to the

same hydrothermal alteration which caused uranium and thorium enrichment, as the only pink phenocrysts seen in lavas have been in a highly altered series on the reservation.

An especially coarse and permeable piece of conglomerate float was found by Dr. Neil Church in the northern claim area. In addition to the wide variety of lithologies mentioned previously, this specimen contains clasts of a leucite-bearing lava.

Leucite was also observed in a clastic rock encountered on the extreme southeast of the volcanic area. This is a very angular multilithic breccia, cemented in part by lapilli of volcanic glass. It appears to be a cone complex or vent facies.

SKAHA RESERVATION

The relationships between units in this area are only poorly known. Most of the reservation is underlain by an apparently normal series of the Marron Volcanics, dipping to the south. On the north these are underlain by a major series of white rhyolites and rhyolite tuffs, which appear to be co-magmatic with the Shingle Creek intrusive - an unusual granite with very large K-feldspar crystals which outcrops in adjacent Shingle Creek Valley. The tuffs locally form a boulder conglomerate which is mapped as part of the Springbrook Formation. Only one small radioactive zone has been observed in these tuffs, and that was at their base.

The major radioactive unit in this area is largely of pink or pink and green colouration, and is comprised of tuffs, grits and volcanic sandstones. Textures vary from eutaxitic to clearly water-laid bedding, and from coarse clastics to fine ash. It appears to lie stratigraphically between the rhyolite tuffs and the lowest member of the Marron Volcanics, which is the Yellow Lake phonolite. The relationships are not as yet clear, however, and have been complicated by dacite dikes and by large bodies of intensely altered pink volcanic rocks.

(a) The Rhyolites

These are nondescript white quartz porphyry tuffs, although they locally contain K-feldspar phenocryst fragments similar to those of the Shingle Creek Intrusive. The tuffs appear to have filled in an irregular terrain (in part as matrix to a boulder conglomerate) and do not seem to be involved in the steep but local northward dip of the later rocks.

Thin sections suggest that the lower members of these tuffs are less siliceous and comprised of clasts of dacite or rhyodacite lavas. There is a wider variety of clasts here, and also some calcite and muscovite alterations. Minor amounts of radioactivity have been observed in this basal unit.

A sample of rhyolite tuff submitted for multi-element analysis had a high silica content (over 70%) and surprisingly little potassium, but otherwise there were no chemical peculiarities.

(b) Pink Tuff and Clastic Unit

The strong radioactivity of these rocks is apparent in the average of 65 ppm uranium and in excess of 300 ppm thorium from samples analysed by both delayed neutron activitation and gamma spectrometry. Thin section and staining have indicated a wide range in composition as well as texture,

despite the apparent thin nature of the unit. Rhyolite or quartzose fragments are absent in some sections, yet form a major portion of others. Some appear to be lapilli tuffs of a single composition, while others are multilithic breccias which include syenite and granitic clasts. Some are water-laid, while others appear to be air-fall tuffs or even ashflows.

The pink crystals are K-feldspars and albite, as noted in the Riddle Creek area, but almost all of the clastic rocks in the reservation occurrence have undergone moderate to strong lateration. The most common clasts are of microlite lavas with feldspar, augite and biotite phenocrysts. alteration is dominated by muscovite (sericite), quartz, carbonate and epidote, with some indication that the aerial tuffs tend toward sericitization while quartz-carbonate alteration marks the water-laid grits. The most radioactive rocks have undergone what appears in thin section to be an addition of epidote or zoisite, accompanied by lesser amounts of quartz, carbonate, fluorite and opaque minerals. This is quite similar to alteration affecting the most radioactive felted trachytes at Riddle Creek, and again there is the possibility that some of the zoisite is in face secondary allanite. One expecially instructive specimen showed clasts or lapilli of different rocks with different alterations (sericite, argillite, quartz-carbonate), but they had all undergone a zoisite-fluorite alteration during a presumably later, post-depositional, hydrothermal stage.

Two samples from this unit were submitted for multi-element analysis. The first was a multilithic water-laid grit with zoisite-fluorite alteration. Chemically this correlated quite closely with the felted and porphyritic syenites and ignimbrite of Riddle Creek, and it was also similar to

radioactive pink grit of the Clark property. It was not, however, particularly close to the composition of the other specimen from its own unit, which was an airfall tuff or ashflow with muscovite, carbonate, quartz, zoisite and fluorite alteration products. In hand specimen the epidote alteration takes on a cellular pattern. Its most striking feature in thin sections, however, was crystals with the optical properties of clear, red corundum - i.e. ruby.

Chemically, this sample did not particularly closely resemble anything else, its most striking feature being a 6.2% fluorine content, coupled with high lead and zinc values. Its closest relatives chemically are again the ignimbrites and trachytes at Riddle Creek.

(c) Altered Flows

To the north of the major radioactive showing on the Skaha Reservation there is a similar series of tuffs and grits which are moderately radioactive and which are associated with moderately radioactive pink, altered volcanics, rather than the rhyolites. In this area there is also a major zone of orange to pink highly altered volcanics which appear to be an alteration belt of some sort. In view of the possible connection between these volcanic rocks and the radioactive pink tuffs, a sample of both alterations was examined in thin section and through multi-element analysis.

The lava directly associated with the tuffs and grits was almost entirely destroyed by carbonate alteration, with little more than some of the albite crystals remaining. There was also considerable hematite, suggesting that the altering solutions were oxidizing, and unusual amounts of apatite were observed. The sample from the main alteration belt was quite similar, with almost complete carbonate

alteration (no quartz) and high apatite content. More sericite was involved in this case and augite was still recognizable. There was also texture suggesting a late stage cataclasis or stress. Chemically, both rocks had similar compositions, being of roughly 46% silica and having unusually high levels of such elements as Fe, Cr, Ni, Co, Ag, Ba, Sr and P. This assemblage makes them correlate closely with the Yellow Lake (rhombic porphyry) phonolites rather than with the trachytes or radioactive tuffs. The altered lavas probably underlie the radioactive sediments, and may be equivalent to the phonolites which appear to underlie the radioactive grits on Clark property as well. More work is required in both areas to determine the volcanic sequence.

CLARK PROPERTY

In this area a major sequence of classic rhombic porphyry phonolites of the Yellow Lake member overlie a complex of non-radioactive rhyolite tuffs and breccias. This complex appears to include a variety of lithologies, including ignimbrite, and it in turn overlies a variable thickness of the Springbrook conglomerate. The basement rock in this area is normal granitic country rock in some places, but under much of the extrusive sequence there is an unusual body of pink aplite or a coarser grained pink alaskite.

Radioactive grits form what appears to be a large channel deposit within an otherwise grey bed of tuffs and sandstones. In places this bed appears to lie between the phonolitic sequence and underlying explosive rhyolite deposits. Elsewhere, however, the tuffs and sandstones occur between volcanic flows. There may be more

than one horizon involved. Thin section work has not been as extensive on this property as for the other two occurrences, due to the complexity of the rocks and the lower uranium contents.

(a) Springbrook Formation

This is dominantly a multilithic cobble conglomerate with very low porosity (due to silica cementation), and also of low radioactivity. The cobbles are largely of granites, cherts and greenstones in this area. It is a cliff-forming unit of irregular thickness.

In the northern portion of the Clark claims the Springbrook is typically fine grained, being dominantly a sandstone or grit, and hence more applicable to thin-section study. This showed that the clasts themselves had undergone a wide variety of alterations, including the carbonate, kaolin and sericite varieties. Much of the matrix was argillic, but the rock as a whole had undergone a hydrothermal alteration phase, which caused silicification and kaolinization of the matrix and chloritication of some of the clast rims.

(b) Altered Rhyolites and Breccia Sequence

This highly varied rock group is dominantly of red and white colouration and includes flows, ignimbrite, tuffs and explosive breccias. Some are, in fact, rhyolite grits similar to those of the Indian Reservation, but others were found to contain nephaline instead of quartz. One minor block flow contains leucite. For the most part, however, these rocks have been so thoroughly destroyed by quartz-carbonate alterations that it is difficult to determine the original composition. This area was likely close to the source of explosive volcanism. One classic multilithic breccia appears (in thin section) to have been shattered by two explosive events, the first followed by

silicification and the second by carbonate alteration. Fresh biotite occurs in many of the specimens, and potassic alteration may be seen in stained specimens. The red and brown colours of many of these lithologies is due to extensive hematite which accompanies the other alterations.

This sequence lies directly over the basement granite or aplites in some places, and includes these rocks in some of its breccias. The only radioactive zone discovered in this lithology was near such a basal contact and was due almost entirely to thorium.

(c) Radioactive Pink Grit

Only two samples of this rock were examined in thin section, as most of its occurrences on the Clark property were not discovered until this spring. As with the other pink grits, it is comprised of clasts of microlite lava mixed with crystals of K-feldspar and albite. Quartz crystals are rare, although there has been some silicification of the matrix. Fresh biotite is common, and pyrite more common than in other occurrences. Hematite dust is widespread in the unit.

The grits appear to comprise one or more large channel deposits in a moderately radioactive bed of shaley tuffs and volcanic sandstones. This unit is almost flat lying (dip slightly to west) and in some areas at least occurs between phonolite flows rather than under that sequence. More work is required to determine the stratigraphy here. Near the grid base station there is a large area of brown, moderately radioactive alteration of tuffs and flows adjacent to (largely underneath) the channel.

The uranium values from Clark samples have not been encouraging to date, although one case showed substantial enrichment of uranium daughter products. Other small radioactive zones have also been encountered on the property, including one in the aplite, a thorium-rich lamprophyre dike, and two zones adjacent to major dacite dykes.

GENERAL GEOCHEMISTRY

Uranium and thorium analyses for various rocks are given in the accompanying table. Wide differences may be observed between the results from different laboratories and methods. In part this reflects continuing inter-laboratory discrepancies and a general lack of reproducibility for analyses of these elements. It should also be remembered, however, that the Min-En results are based on leaching procedures which do not extract 100% of the elements. Furthermore, in some cases different pieces of the specimen were involved in the different analyses.

The degree of disequilibrium between uranium and its daughter products is extremely variable. It would appear that in general uranium is more easily leached than its daughter products in surface exposures of radioactive lavas and syenites, while the reverse is true for the channel grits. The extreme daughter excess in FM54 involves a seep, and may represent radium accumulation. The generally lower values of Pb²¹⁴ as compared to radium are presumably due to escape of the intermediate radon during pulverization.

The multi-element analysis failed to show any really distinctive assemblage of elements associated with uranium and thorium in

these rocks. Most of the strongest correlations with uranium for the 22 volcanic samples analyses for 18 elements were negative correlations and represented elements closely associated with the phonolitic influence (Cr, P, V, Mg, Ti, Al, Ba and Sr). The elements having the closest overall positive correlation with uranium are Zn (.69), Be (.40), K (.46), Pb (.37) and fluorine (.31). Of these, the lead and the fluorine are associated more directly with the acid exchangeable portion of the uranium.

ADDENDUM - JUNE 1978

Between writing and release of this report, several new pieces of data have been received of interest. These are presented in list form.

- 1. An electron microprobe scan by The B.C. Ministry of Mines was made on a sample of the radioactive felted trachyte. This showed that uranium occurs in conjunction with manganese, strengthening the belief that uranium is associated with the opaque minerals deposited hydrothermally. More of this is planned.
- 2. Dr. N. Church of The B.C. Ministry of Mines further reported that a tuff sample taken from below the rectangular porphyry trachytes on the Agur-Ash property had been hydrothermally converted to as high as 40% zeolites. This is especially interesting in view of the role of zeolites in Japan in trapping uranium.
- 3. In view of the fact that radioactive elements associated with alkaline rocks in some areas (Brazil for example) are located in zircons, zirconium analyses were ordered with the multi-element work. The results did not arrive until after the report was completed, but only one rock (a felted trachyte) had anomalous quantities. Zircon crystals were not commonly met in thin section, either, and pleochroic halos in biotite were not observed.

- 4. A larger number of rocks have now been examined by low energy gamma spectrometry, largely due to spring mapping. This grids an average of 50 ppm uranium and 224 ppm thorium for the 14 samples of rectangular trachyte flows (those not hydrothermally leached). The eight felted trachyte specimens average 131 ppm uranium and 307 ppm thorium, while five boxwork syenites averaged 55 ppm uranium and 316 ppm thorium. These rocks tended to have fairly large disequilibrium coefficients, presumably due to leaching of uranium daughter products.
- 5. This spring, a rectangular porphyry trachyte dyke was observed cutting rhomb porphyry phonolite (Yellow Lake Unit) flows on the northeastern Agur-Ash property. As with the radioactive grit channels, the radioactive trachyte now appears to postdate at least the earliest phonolite volcanism.
