LOCATION MAP, RUST CLAIMS
ATLIN MINING DIVISION, NTS 10⁴N

OCTOBER, 1978.

Map 1

SUMMARY AND CONCLUSIONS

United Rayore Gas Limited acquired the Rust mineral claims in 1977. The claims are in the Cracker Creek drainage area about 30 kilometers northeast of Atlin, B.C.

R.H. Seraphim Engineering Ltd. undertook radiometric, geochemical and geological surveys of the claims during September, 1978 to evaluate their potential for uranium. The program is only partially complete.

The claims lie near the western margins of the Surprise Lake alaskite batholith, and are underlain by alaskite and older Paleozoic rocks. Kasolite, a secondary uranium mineral, was found on quartz float in the cirque near the northwestern boundary of the Rust claims. The quartz float is believed to have originated in a zone of quartz and silicified alaskite near the contact between alaskite and ultramafic rocks. One or two limonitic areas that are associated with malachite in the zone are also radioactive, about twice background over a few square centimeters. Uranium mineralization is associated with quartz at other locations in the batholith.

The radiometric survey revealed a uranium + thorium count ranging from about 20 to 66, for the areas underlain by alaskite. Some of the higher counts may be important, and those, particularly in areas with higher

uranium geochemistry (>10 ppm U.), should be examined more closely.

The amount of leaching, i.e. removal of radioactive material from surface, remains a problem which might be partially solved by trenching.

RECOMMENDATIONS

The survey work completed to date covers only part of the Rust claims. Other radioactive occurrences are known in the vicinity of the claims, therefore the survey work should be extended, where practicable, to cover the remaining ground.

The lower end of the quartz vein stockwork in the cirque area should be drilled and blasted to obtain a better appreciation of the nature of the mineralization and amount of surface leaching. The vicinity of the quartz stockwork, and the indicated areas of geochemical and radiometric interest should be prospected further.

INTRODUCTION

United Rayore Gas Limited acquired the Rust mineral claims in 1977. A program of geological, geochemical and radiometric surveys was initiated during September 1978 to evaluate the property's potential for uranium.

The exploration target on the claims is tabular vein-type deposits similar to those being mined in Western Europe and more particularly in France. Uranium mineralization in these deposits is present in silicified veins within the granite and is in many places accompanied by fluorite and minor carbonate. The principal uranium mineral is pitchblende which is commonly associated with minor pyrite, marcasite and iron oxides.

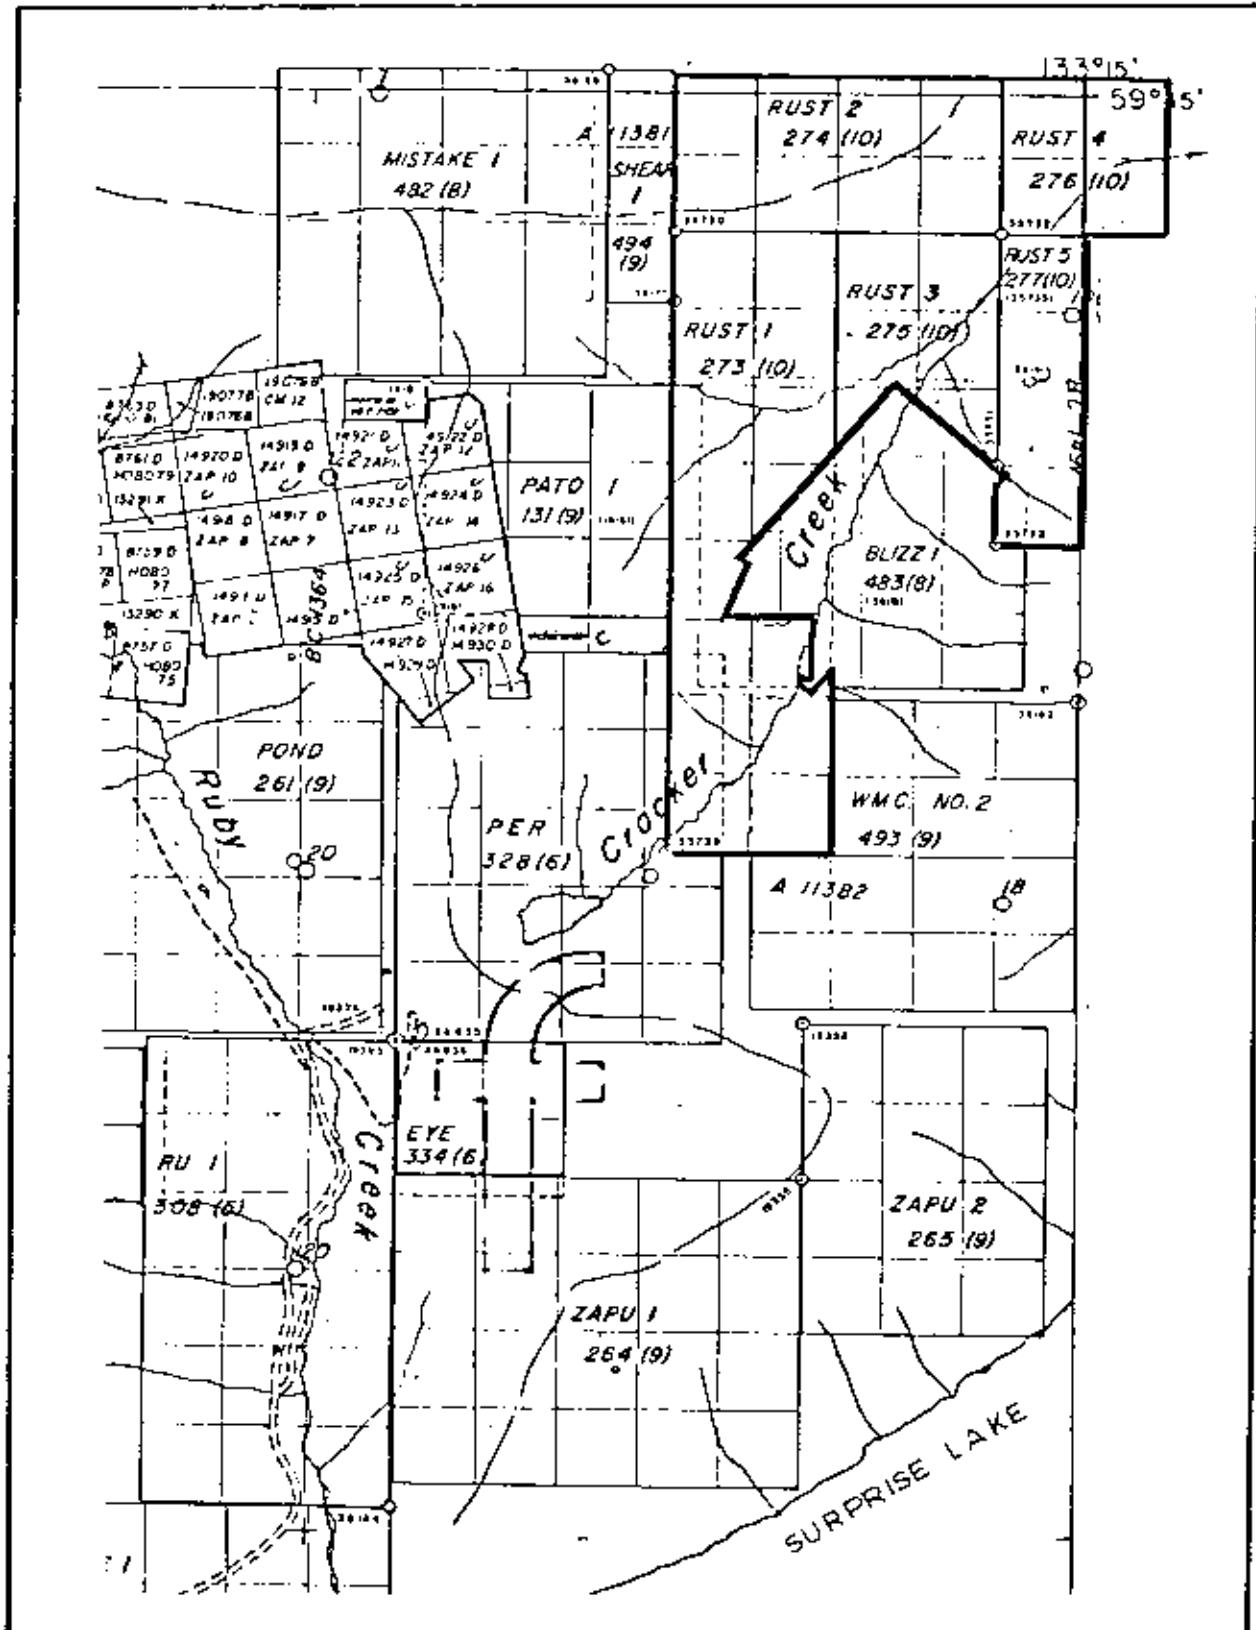

Due to the lateness of the season and inclement weather, the full program was not completed. The results of the work completed to date are described herein and presented on maps 3 to 5 at scale of 1 : 4000.

LOCATION AND ACCESS

The Rust claims are located in the Cracker Creek drainage area approximately 30 kilometers northeast of Atlin. Access is by good gravel road from Atlin to Pine and Ruby Creeks, thence by a rough four-wheel drive road northeast along the Cracker Creek Valley.

The northernmost Rust claims are centered roughly on Latitude $59^{\circ} 45'$, Longitude $133^{\circ} 15'$ and most of the claim block is in N.T.S. 104W/11W.

Elevations range from about 900 to 1800 meters above sea level. The terrain is marked by broad valleys,

RUST CLAIMS - INDEX MAP.

Map 2

subdued upland glaciated surfaces and moderate to steep valley slopes. Some of the creek headwater in steep precipitous cirques.

CLAIMS

The property, owned by United Rayore Gas Limited, is comprised of the following claims in the Atlin Mining Division:-

Name	Record	Units	Group	Anniversary
Rust 1	273 (10)	16	Rust	October 5/78
Rust 2	274 (10)	8	"	"
Rust 3	275 (10)	6	"	"
Rust 4	276 (10)	4	"	"
Rust 5	277 (10)	4	"	"

The claims have not been surveyed.

HISTORY AND BACKGROUND

Barymin Company investigated radioactive occurrences on claims near the head of Cracker Creek in 1955. Barymin's claims covered rusty weathering alaskite containing secondary uranium minerals zeunerite and meta-zeunerite. The mineralization is in kaolinized fracture zones up to 4.5 meters wide which are present in and near the marginal finer grained phases of the intrusion. A number of quartz veins are present and the mineralized

area is locally marked by fluorite, pyrite, arsenopyrite and chalcopyrite. The highest grade sample selected from one of the zones investigated yielded 0.088% U_3O_8 and 0.011% $Tungsten$.

Much of the recent exploration in the Cracker Creek - Ruby Creek area has been for tungsten and molybdenum. The Adanac molybdenum deposit has reserves of 94 million tonnes grading 0.16% molybdenite. A number of other smaller deposits, including the Pit copper prospect on the Rust claims, have also been investigated.

A resurgence of interest in uranium prompted the federal and provincial governments to undertake, jointly, a multielement geochemical survey of Atlin map sheet 104N in 1977. The data produced from this work showed that the Surprise Lake alaskite intrusion contains highly anomalous uranium, in relation to surrounding formations.

From 1976 to 1978, other companies investigated radioactive occurrences near Cracker Creek, and at other locations underlain by alaskite. One drill program was recently completed in the Trout Lake area east of Cracker Creek.

WORK PROGRAM

Radioactive float was found near the western boundary of the Rust 2 mineral claim. An irregular grid was established by hip chain and compass to survey this area in detail.

A base line was run north and south from the legal corner post of Rust 2 mineral claim. Grid lines 100 meters and 200 meters apart were run easterly with stations marked at 50 meter centers. One line at 100S had stations marked at 100 meter centers. Approximately 15 line kilometers of geological, geochemical and radiometric surveys were completed.

RADIOMETRIC SURVEY

A radiometric survey was carried out over the grid with a Sirthey GIS 4 gamma-ray spectrometer, Serial number 704128.

The survey procedure involved placing the instrument on the ground next to the station and taking three sets of readings of 10-second duration. The readings were for (1) total count, (2) uranium and thorium, and (3) thorium. All of the records shown on Map 4 are the average of three readings.

Readings for uranium and thorium recorded in areas underlain by alaskite vary from about 20 to 66. The variability is due in part to contained radioactive material and to the amount of surface cover. Some of the higher readings near the northwest corner of the claims, and, on and near line 250 south might be rechecked as they occur in the general area of weak geochemical anomalies.

The intruded rocks display a much lower radiometric profile than the alaskite and the survey consequently is useful in interpreting geology.

GEOCHEMICAL SURVEY

Soil and silt samples were collected from the grid stations shown on Map 5. Some stations were not sampled because they are either on outcrop or in areas covered by talus or boulders. These areas are more prevalent at the upper elevations.

Soil horizons on the upper slopes are not well developed and "B" horizon soils are uncommon. A typical sample from these areas might consist of brown fine to coarse sandy soil mixed with minor amounts of surface "A" horizon soil if it is present.

The soils in the valleys are usually darker, contain an assemblage of clay, silt and sand and are in most places more organic.

Samples were collected with grub hoe or soil auger. The samples were packaged in standard brown kraft soil envelopes and shipped to Chemex Laboratory in North Vancouver. Details on the type, depth of sample and sample description are shown in Appendix 2.

At Chemex the samples are dried and screened. A portion of the -80 mesh fraction is ashed and digested in hot nitric acid, and evaporated " dryness. The residue is leached with a known volume of dilute nitric acid. It is then mixed, and a small aliquot pipetted into a platinum dish for evaporation and fusion with a carbonate-fluoride flux for measurement of uranium fluorescence. The detection limit is 0.5 ppm. In some instances, as shown on the certificates of analyses, the detection limit varied due to fluorescence quenching caused by high concentration of interfering metals.

Most of the samples yielded less than 5 ppm U. The area underlain by alaskite displays a much greater geochemical variation than the intruded rocks. Samples yielding greater than 5 ppm U are generally scattered within the grid and isolated.

A number of samples collected by auger along Cracker Creek, and silt samples on Line 1100 south yielded between 11 and 95 ppm U. Field data indicates that many of these samples contain some organic debris which might provide the higher uranium content.

GENERAL GEOLOGY

The Rust claims are located near the western margins of the Surprise Lake alaskite batholith. The geology near the western end of the intrusion is complex. The batholith is Cretaceous (?) in age but the Adanac molybdenum deposit occurs in a complex Early Tertiary stock a few kilometers southwest of the Rust claims. The batholith intrudes Cache Creek sedimentary and volcanic rocks, and ultramafic rocks of the Atlin intrusions. Remnants of Tertiary and Quaternary volcanic rocks are evident in the Ruby Creek area near the headwaters of Cracker Creek.

The alaskite is comprised mainly of potash feldspar, plagioclase and quartz with up to 5% biotite. Textures vary from fine to coarse grain in porphyritic and non-porphyritic rocks. The fine grained alaskite locally has sharp boundaries and occurs as narrow dikes, elsewhere contacts are gradational. Quartz porphyry, quartz feldspar porphyry and green volcanic dikes up to a few meters wide are also present in some areas.

The alaskite contains abundant smoky quartz, minor amounts of muscovite, fluorite, apatite, beryl, and rare topaz and allanite. Quartz veining is locally evident and small zones of simple pegmatite are present. The alaskite forms soft crumbly outcrops in many places and is locally limonitic due to the weathering of minor

pyrite, arsenopyrite, chalcopyrite, and magnetite; and to the decomposition of biotite.

GEOLOGY OF RUST CLAIMS

Remnants of Cache Creek volcanic and sedimentary rocks are closely associated with larger masses, possibly pendants, of serpentinized ultramafic rocks around the cirque area on the Rust 2 mineral claim. Radiometric and geochemical data indicate that these rocks may underlie a larger area than that shown on the maps.

The main easterly trending creek in the cirque probably marks the northern contact of the southern mass of ultramafic rock. This contact, likely fault controlled, includes a complex zone of quartz and silicification trending easterly. This zone is believed to be the Pit copper prospect shown on mineral inventory map 100' (XI).

The quartz zone is incompletely exposed, has been traced along the valley bottom about 85 meters, and at one place is about 12 meters wide. The individual quartz veins in the zone are in many places vuggy, locally more than one-half meter wide and of different strikes. Near the western end, most of the veins strike N15° - 20°E with some at N30°W. Quartz stringers striking N50°E are prominent in the central section as are thick quartz veins with parallel stringers trending about N70°-80°E and dipping 70°S. N70°E vertical veining is the more pronounced

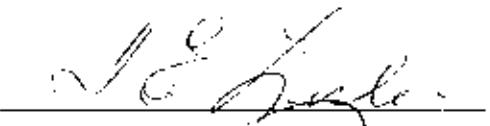

at the easterly end of the zone. The stockwork is cut by late N20°-30°W steeply dipping fractures and may be locally offset by them.

The zone is weakly limonitic with minor manganese and hematite. It is more limonitic towards the eastern end where minor malachite is also present. One or two of these limonitic areas with malachite are radioactive, about twice background, over a few square centimeters.

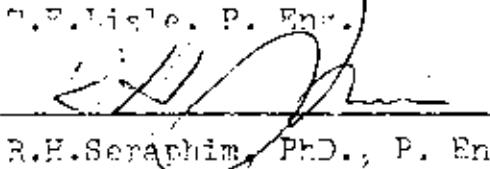

A 40 centimeter slab of quartz float was found about 50 meters downslope. A slickensided face on this slab is partly coated with kasolite (lead uranylsilicate). The slab probably originated in the lower part of the quartz zone, particularly in the area of larger veins.

A better appreciation of the value of this zone would be gained initially by drilling and blasting a trench across the limonitic material near the bottom exposure. Although bedrock is obscured downslope from the quartz, the trace of the zone might be followed by carefully prospecting the valley bottom with geiger counters.

APPENDIX 3

STATEMENT OF QUALIFICATIONS

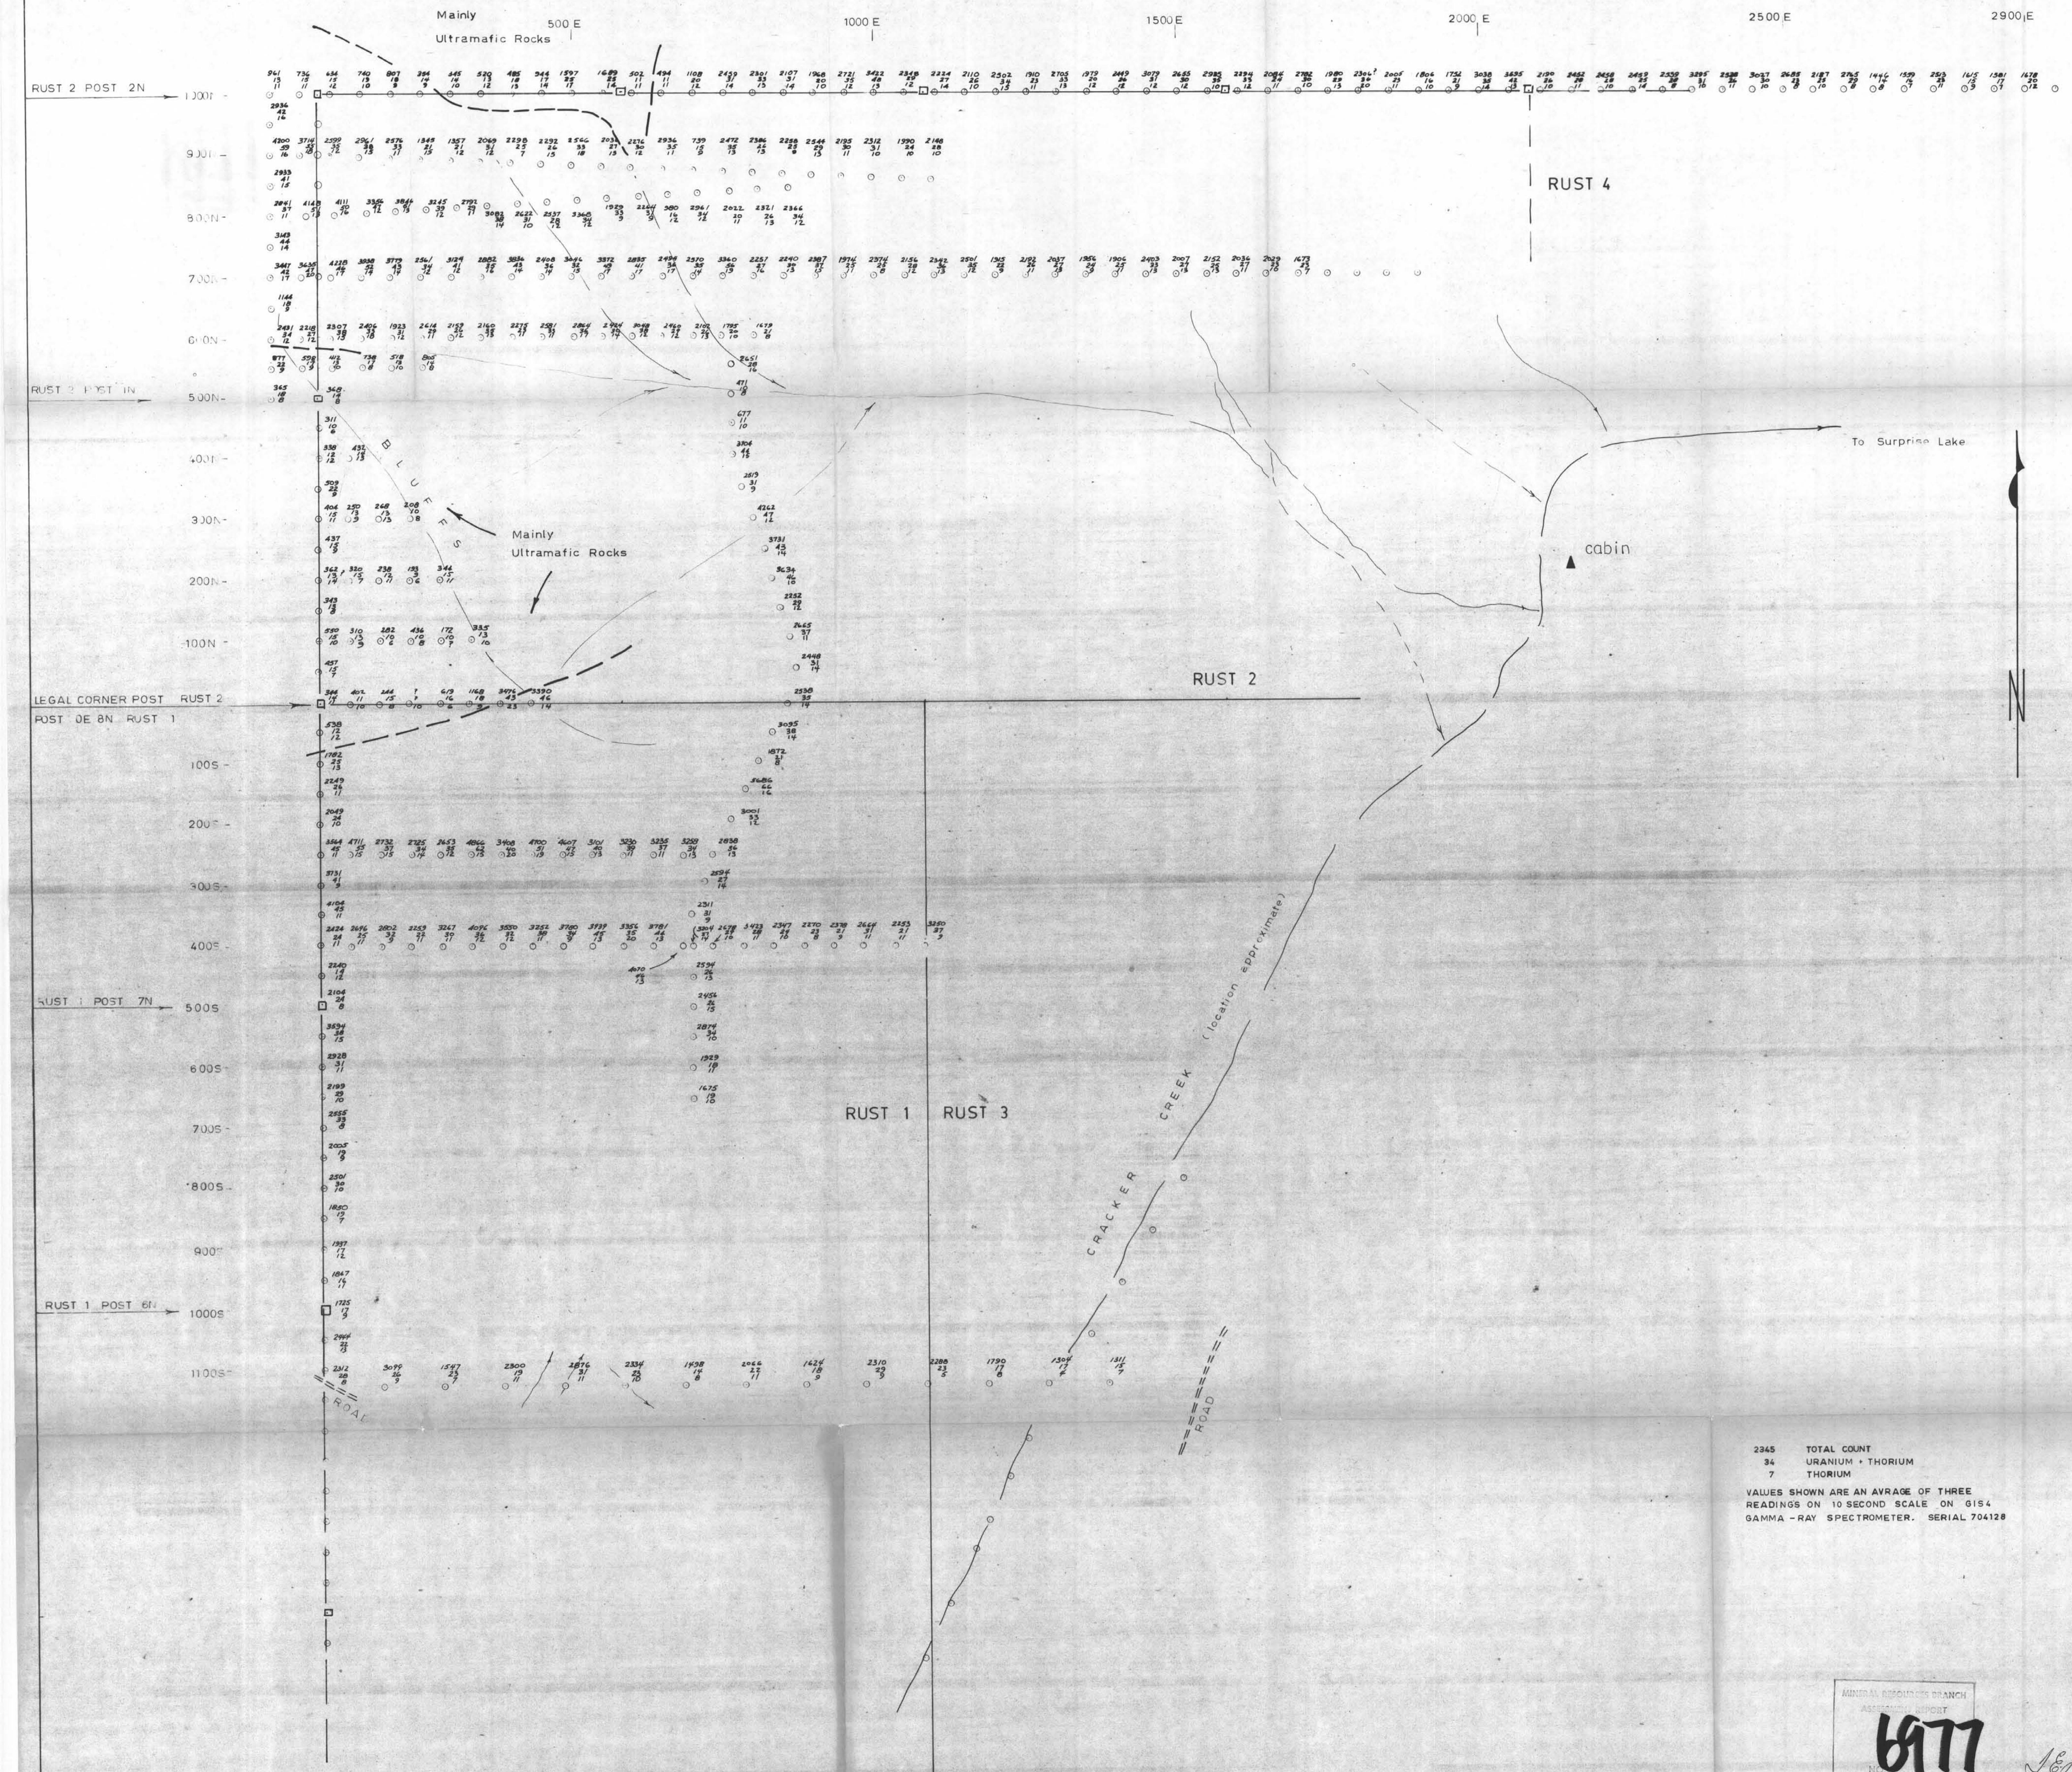

CERTIFICATE OF QUALIFICATION

I, T.E. Lisle of 145 West Rockland Road,
North Vancouver, B.C. declare that:

1. The work described in this report was carried out by me and by the personnel listed in Appendix I under my supervision during September, 1978.
2. I am a graduate of the University of British Columbia with a B.Sc. 1964.
3. I have worked intermittently in exploration geology for several years prior to 1964, and have worked continuously in the same field since that date.
4. I am a member of the following organizations:
 - [a] Canadian Institute of mining & Metallurgy
 - [b] Geological Association of Canada
 - [c] Association of Professional Engineers of B.C.

T.E. Lisle
T.E. Lisle, P.Eng.
October, 20, 1978.
