1. INTRODUCTION

Soil and stream sediment geochemical and ground magnetometer and VLF - EM surveys were conducted by Placer Development Limited during the period of 4 August to 5 October, 1982 on Alpen Exploration Ltd.'s mineral claims at Squamish, B.C. The results of this field work are presented for submission of assessment work on the claims.

2. SUMMARY

A total of 755 soil and stream sediment samples were collected and analyzed for Cu, Pb, Zn, Ag and Au content. Results from the grid pattern of soil sampling show several broad zinc anomalies; more restricted copper and lead anomalies are outlined within the more prominent zinc anomalies. Gold and silver contents are predominantly non-detectable in soil samples and no anomalous patterns are indicated. Numerous stream sediment samples from main drainages and subsidiary tributaries showed significantly anomalous zinc and copper and to a lesser extent lead contents, especially from those drainages that originate within or cross-cut soil geochemical anomalies.

Approximately 25 km of ground magnetometer and VLF -EM data were collected on the property along the geochemical grid lines using a nominal data interval of 12.5 meters. Several strong conductors were encountered some of which correlate with topographic features. Few responses show any line to line correlation at the line spacing used.

Cost of geochemical and geophysical surveys was \$45,685.68.

3. PROPERTY DEFINITION

Property is 16 km east of Squamish, B.C. at headwaters of Raffuse Creek which is a tributary of Mamquam River. The spatial position of seven mineral claims for this property is shown on index map.

Alpen Exploration Ltd. initially conducted basic prospecting and sampling of attractive surface exposures near the southeast corner of the present property. The first claim staking in 1979 was followed by additional staking in the same year and in 1980 as favourable results together with information on general geologic setting became available. This firm continued exploration in 1981 on several mineralized zones on the property.

Placer Development Limited optioned the property from Alpen Exploration Limited in 1982 for purposes of exploring economic mineral potential of the property. All field work for geochemical and geophysical surveys as presented in this report were co-ordinated and undertaken by Placer Development Limited personnel.

4. TOPOGRAPHY AND ACCESS

Property is in heavily-timbered rugged mountainous terrain that is characteristic of coast mountain physiography. General land form at the property is dominated by a steep-sided mountain. Topographic relief from Raffuse Creek, that forms the main drainage, to the mountain peak is 750 to 775 m; the mountain peak rises to 1526 m elevation (see appended map). Mountain slopes and valley floors are heavily-forested and parts of the valley have been logged. Portions of the valley flanks are very steep at 35 to 45 degrees, but for most part these steep slopes are also forested rather than cliff forming. The crown of the mountain is characterized by rounded rolling terrain on which local alpine-type meadows are a common feature. The mountain is cornered by four deeply-carved glaciated valleys. Headwaters of these drainages are in the form of a broad arcuate cirque. Local stream gradient is comparatively steep resulting in development of steep canyon-like ravines. A network of numerous subsidiary small drainages are formed on the steep valley flanks. These streams, many of which have only seasonally intermittent flow are characterized by deep narrow gullies, mini-canyons and small waterfalls.

A network of well-maintained logging roads from Squamish provided excellent access to the property. Approximately 80% of the field work on this project was conducted from these access roads. Helicopters were utilized for part of the program when work was concentrated on crest of the mountain.

5. ECONOMIC ASSESSMENT

Alpen Exploration Ltd. prospected and concentrated their exploration work over five separate mineralized targets on their mineral claims. Additionally a widespread pattern of soil, stream sediment and rock chip sampling complemented the sampling of mineralized zones. This early field work outlined several Cu-Zn geochemical anomalies with superposed but slightly more erratically distributed Pb, Ag and Au anomalies.

General property geology has a sequence of volcanic rocks, correlative with Jurassic Gambier Group, overlying leucocratic granodiorite in the form of a roof pendent. Pyrite, chalcopyrite and sphalerite with minor galena are frequently associated with quartz in narrow faults and shear zones in volcanic rocks. Pyrite and minor chalcopyrite also occur as disseminations and fine fracture fillings in silicified rhyolitic to andesitic volcaniclastic units. Intrusive granodiorite is dominantly unaltered but is locally sheared, altered and mineralized by pyrite.

The geochemical soil sampling program was planned and conducted so as to assess and delineate possible targets. The geophysical surveys were planned to provide information on faults and distribution of lithologic units.

6. GENERAL GEOLOGY

Jurassic Gambier Group volcanic rocks overlie younger intrusive granodiorite as a roof pendent. Preliminary interpretation has indicated an elongated oval-shaped pendent that roughly conforms to the west-northwest trending crest of the mountain. There is evidence that it is a steep-sided keel-shaped body approximately two by one km in size. A much smaller separate outlier of volcanic rocks is exposed near the confluence of A - Creek and Raffuse Creek. (see Generalized Property Geology map).

The volcanic rock sequence consists primarily of light grey and green rhyolitic and dark green andesitic volcaniclastic units. The rhyolitic unit for most part occurs as a peripheral

rind around the roof pendent. A subcircular complex mixture of coarse fragmental agglomerate and poorly-banded tuff and tuffaceous agglomerate is centered in the pendent and forms the topographic crown of the mountain. Angular to subrounded fragments of dark to bright red jasper occasionally form inclusions in andesitic volcaniclastic unit and also occurs as fragments in breccia float.

The intrusive granodiorite is coarse-grained, blockily fractured and usually unaltered. Proximal and along the contact with volcanic rock, granodiorite is often highly shattered and partly altered by chlorite and kaolinite.

Numerous narrow one to ten meter wide rhyolite, dacite and andesite dykes intrude granodiorite. Late-stage vesicular and amygdaloidal basalt dykes have been observed near intrusive-volcanic rock contact. These soft, highly chloritized dykes are intruding granodiorite and also Gambier Group rocks.

7. GEOCHEMICAL SURVEY

Geochemical survey consisted of grid soil and stream sediment sampling program over approximately 75% of the mineral claim area. Field work for this phase of exploration program was conducted during period 4 August to 5 October, 1982.

7.1 SOIL GEOCHEMICAL SURVEY

Alpen Exploration Ltd.'s field results pointed to five separate geochemical and mineralized targets. The soil sampling for this program was designed to obtain more information for the section of the property on which more promising targets were located.

A detailed contour map of the property provided the control for locating and plotting the baseline and grid system. Soil samples were collected at 50 m intervals along north-south lines that were generally spaced at 200 m. Several more closely-spaced fill-in lines and extensions to lines were added to complement the regular grid pattern.

7.2 SOIL DEVELOPMENT AND GLACIATION

Glaciation mainly in the form of valley glaciers has had pronounced effect on terrain development and subsequent soil development. Ice movement from the crest of the mountain and down the respective valleys have left a train of lateral moraines, local terraces and kettle features in the valley floor. Several deep road cuts and creek banks provide excellent exposure of several types of glacial deposits varying from unsorted morainal till, boulder clay and gravel, and stratified glaciofluvial deposits.

Soil development on the property is variable depending on terrain and groundwater conditions, but in general the soil horizons are well-defined. The important B₁ horizon is usually rusty red to bright orange red to brown. The depth and development of overlying A horizon are however variable. In particular, the leached A₂ horizon is often 10 to 25 cm thick for certain areas whereas it is totally absent in other locations or even at the next sample site.

The deep overburden features are generally restricted to valley bottoms and their lower slopes. Soil is normally well-developed on the steep valley flanks which locally attain 40 degrees slopes. Overburden is relatively shallow on these steep slopes. In many stream gullies that down-cut to bedrock, overburden is only one to three meters deep. Evidences of soil slumping or creep have been observed on steep slopes where duplicate soil profiles are developed. Overburden on the more gently sloped upland regions is also relatively thin. The leached A₂ horizon is deeper than normal at these higher elevations where groundwater movement is locally more restricted.

7.3 VEGETATION

Valley bottoms and flanks are heavily-forested. Hemlock is dominant coniferous species; balsam and more locally in poorly-drained areas, cedar and spruce are intermixed with hemlock. A variety of underbrush including huckleberry, rosebush, ferns and locally Devil's Club and skunk cabbage cover the ground surface. On the upland regions, hemlock and lesser amounts of balsam still prevail as small stands and clusters. Stature and general growth of trees are stunted at these higher elevations. Alpine-type meadows are a common feature at this level, and these generally support huckleberry bushes, buckbrush, some grass

and two varieties of heather.

Much of the lower slopes have been logged in the past two to four years. This may affect geochemical interpretation of some samples, especially on the western slope of mountain where logging slash was burned. Fireweed prevails in logged-out areas.

7.4 SOIL SAMPLING

Soil samples were collected from small holes that were dug to depths varying from 10 to 40 cm. In most cases, samples averaging 150 gm were collected from B1 horizon and emplaced in a numbered kraft paper envelope. Sampling was frequently hampered when excessive depths of A1 and A2 horizons were encountered at the sample sites.

7.5 STREAM SEDIMENT SURVEY

A series of stream sediment samples was collected from main creeks and numerous small tributary streams and seepages that are draining area of interest. A number of small streams intersected the soil sample lines, and in these cases a sediment sample was normally collected from the stream. Fine silt and sandy material were abundant in the larger creeks; more gravelly sand and silt were available in the smaller streams where gradient is much steeper. Small seepages occur near the toe of talus and colluviated debris slopes. The sediment from these seepages was also sampled.

7.6 DRAINAGE CHARACTERISTICS

The property can be considered as being drained along two main westerly-flowing systems of which the one nearer the north end of property is referred to as A - Creek. Both of these creeks join the larger northerly-flowing Raffuse Creek (see appended map). Another large drainage system flows to the southeast. The two former drainage systems have a well-developed dendritic pattern of subsidiary streams that were available for sediment sampling. These tributaries flow along extremely steep gradients and parts of many are down-cut to bedrock. Flow in some streams are reduced to only a trickle or become dry during parts of the year. Other smaller streams often disappear into the ground

under talus and colluviated debris prior to emerging at the toe of the slope as seepage.

Sampling of subsidiary streams on A - Creek was moreorless restricted to the more geologically favourable southside. Accordingly, sampling of tributaries along the drainage system on south border of property was concentrated on the southwesterly-flowing tributaries.

7.7 ANALYTICAL PROCEDURE

All soil and stream sediment samples were assayed by Placer Development Limited Geochemical Laboratory at Vancouver, B.C.

7.7.1 ANALYSIS FOR Cu, Pb, Zn AND Ag

Samples are dried in a hot-air dryer, then sifted in -80 mesh nylon sieves. A 0.50 gm portion of -80 mesh fraction of soil or sediment is weighed with a precision torsion balance. Samples are digested in hot solution of HNO_3 and HClO_4 for three and a half hours, then cooled, diluted and prepared for analysis on Perkin-Elmer 603 Atomic Absorption Spectrophotometer for Cu, Pb, Zn and Ag.

Detection limits and ranges are listed below:

<u>METAL</u>	<u>DETECTION LIMIT & RANGE</u>		
Copper	2	-	4,000 ppm
Lead	2	-	3,000 ppm
Zinc	2	-	3,000 ppm
Silver	0.20	-	20 ppm

7.7.2 ANALYSIS FOR Au

Following the drying and sieving process, a 3.0 gm portion of -80 mesh fraction is heated at 600 degrees Celsius for one and a half hours, then HBr solution is added and allowed to stand overnight. Water and MIBK solution are added, shaken, centrifuged and then 1% HBr in water is added to the top organic layer

separate. Solution is shaken prior to analysis for Au by atomic absorption. Detection limit and range are 0.02 to 4.00 ppm.

7.8 RESULTS

Geochemical assays for Cu, Pb, Zn, Ag and Au are plotted on appended maps. With reference to the maps, soil sample sites are designated by a small circle symbol, and stream sediment samples by a small triangle. Sample numbers are not plotted on the maps as the samples were identified by their grid location in the field.

Soil sample results generally indicate the following geochemical features.

- i Several broad zinc anomalies are centered at fairly high topographic elevations on the north, south and southeast facing slopes of the main mountain. Another anomaly with a long downhill dispersion pattern is located on the west-facing slope. Two smaller anomalies are situated at lower elevations close to road-crossing of A - Creek.
- ii Trend of copper anomalies are more restricted than zinc but spatial location of anomalies closely mirrors the zinc positions. Copper is only signally higher near the A - Creek crossing.
- iii Lead anomaly pattern also follows zinc and copper. However the higher lead centers tend to be much tighter or restricted in size as well as being spatially upslope from copper centers.
- iv Silver and gold were largely undetectable in soil samples. A few slightly higher than normal silver values can be grouped as a subtle zone, and these zones tend to correspond closely to lead anomalies.

Stream sediment values are plotted on the same map as soil values. Within the respective soil anomaly zones, sediment values are accordingly anomalous. In most cases the sediment values are significantly higher than adjacent soil sample values, especially for those streams that are shedding through anomalous zones.

8. INTERPRETATION OF GEOCHEMICAL RESULTS

The main emphasis of this geochemical program was to delineate and evaluate the more promising targets that were discovered by Alpen Exploration Ltd. In particular, special attention was focused into determining the source of original geochemical anomalies and the possible effects of glaciation and steep topography on geochemical dispersion patterns.

The coincident or overlapping position of zinc, copper and lead anomalies is suggestive that metals are being shed from a common source. The large anomalies along south, west and north-facing slopes of the mountain closely approximate the silicified and locally pyritized periphery of the roof pendent. The broadly dispersed anomaly patterns especially for zinc, and to a lesser degree copper are indicative of downslope dispersion. Lead is comparatively immobile, and as a result, the restricted zones of higher lead are possibly proximal to a mineral source. The smaller anomaly that "hangs" on the steep north-facing slope of mountain shows a sharp coincident peak for all three elements. Minor pyrite, chalcopyrite and sphalerite have been identified in a creek exposure. It is noted that soil samples show only limited downslope dispersion for this anomaly, but stream sediments 500 m downhill and at the base of slope are anomalous.

The zinc anomaly at the A - Creek road crossing occurs in an area where an outlier of remnant volcanic rocks have been identified. Copper and lead in soil samples do not support the zinc anomaly. The significance of anomalous Cu and Pb in stream sediments can be attributed, in part, to a narrow mineralized shear zone occurrence.

A small Zn - Cu anomaly occurs approximately 0.5 km east of A - Creek road crossing. Samples at this location were collected from a mixture of morainal and glaciofluvial deposits that have been subsequently cut by small stream gullies and locally covered by colluvium. Source of this anomaly is unknown.

Two main lithologies are recognized on this property, volcanic rocks of the roof pendent and younger intrusive granodiorite. It is noted that general geochemical background for Cu, Pb and Zn is lower in granodiorite compared to volcanic rock. This is best illustrated by copper geochemistry.

9. GEOPHYSICS

Ground magnetometer and VLF - EM surveys were conducted along the soil geochemical grid. A total of approximately 25 line km was completed.

9.1 DATA COLLECTION

Ground magnetometer and VLF data were gathered on 14 lines at a sample interval of 12.5 m (nominal). A Scintrex MP-2 proton magnetometer and a Scintrex MBS-2 recording base station magnetometer were employed for gathering the magnetic data. Magnetometer data was normalized to +/- 5nT (gammas) by applying the diurnal corrections as recorded at the base station on the property.

A Geonics EM - 16, tuned to either Cutler, Maine or Annapolis, Maryland was used for the VLF data collection. These two stations are well suited to be used on the N - S lines; (direction to the stations being 070 degrees and 095 degrees respectively). Two stations were used because of the maintenance (shutdown) schedules followed by the U.S. Navy. Both In Phase (% tilt of the polarization ellipse) and Quadrature (minor axis of polarization ellipse in %) were recorded at each station. Frequently, the actual slope of the traversed line was recorded.

9.2 PRESENTATION OF RESULTS

Both magnetic and VLF data were plotted in profile form on 1:5000 scale base maps. Magnetic intensity was plotted at a scale of 1 cm = 200 nT. In addition, the data was filtered using a 7 point filter along the lines (weights 0.015, 0.080, 0.225, 0.35, 0.225, 0.08, 0.015) preparatory to contouring the data.

VLF data was subjected to the "Fraser" filter. This filter was employed for two reasons. First, it is designed to reduce (if not remove entirely) topographically induced anomalies, and second, the filter converts "crossover" to simple peaks which can be simply contoured; However, the filter does have minor drawbacks; some weak anomalies do not survive the filtering process. In addition, sharp topographic changes introduce weak EM "anomalies". Therefore, the raw In Phase data is always plotted along with

the filtered results. These were plotted in profile form at a scale of 1 cm = 20% IP and 1 cm = 10% for Fraser filtered results.

The standard In Phase / Quadrature profiles are also plotted on a similar base map.

10. INTERPRETATION OF RESULTS

Ground magnetometer data is remarkably uniform, due no doubt to the homogenous nature of the granodiorite making up the bulk of the country rock in the lower parts of the property. Surprisingly however, the volcanic units except in one location are also nonmagnetic. Many andesite dykes were encountered with next to no magnetic response. The basalt between lines 22E and 24E gave very strong (up to 4000 nT) responses on those lines. It is possible that this magnetic feature forms part of the contact between the intrusive in the valley bottom and the roof pendant volcanics on the ridge tops. There is some weak evidence of a series of magnetic events including the above mentioned, near or on the proposed geologic contact. Since the trenched area is very close to the basalt, the two are most probably related.

In general however, detailed magnetic interpretation is nearly impossible as exposures in many of the creeks indicated that many of the andesite dykes were striking sub-parallel to the lines.

VLF data is also not very conclusive. A noise level of +/- 3% exists in the data which degrades the interpretation of the weak anomalies expected from 5 - 10% sulfide stringers as seen in a few of the exposures. This noise level is a direct result of the proximity of the VLF station outside Seattle, Washington, which is so powerful as to partially swamp the ability to get the null response of the other stations. Seattle itself could not be used as it is almost due South, rather than East or West as dictated by the line orientation. The station in Honolulu, Hawaii was also tested in an attempt to get better data but was also swamped by Seattle in addition to being poorly located. Nevertheless, one strong semicontinuous trend is visible over lines 8E 14E. A second weaker series of anomalies is interpreted parallel to the creek between lines 10E and 14E. A single strong anomaly marks the location of a N 20 degrees West striking mineralized shear zone on line 32E at 2 +50S. Other moderate strength anomalies exist; some are due in part to sharp topographic changes but line to line continuity is not evident, possibly because of the wide (200 meter) line spacing.

11. STATEMENT OF EXPENSES

The following expenses were incurred by Placer Development Limited for conducting the geochemical and geophysical surveys on Alpen Exploration Ltd.'s Squamish, B.C. property. Field work was undertaken during the period of 4 August to 5 October, 1982. Compilation and evaluation of results and assessment report preparation were on-going during above period and completed on 15 October, 1982.

---------------------------	---------------------

12. CONCLUSION

Soil geochemical survey indicates that a peripheral silicified and locally pyritized volcaniclastic unit of the roof pendent is a possible favourable lithologic horizon.

Ground magnetometer and VLF surveys did not identify any new targets. The geologic contact of the roof pendent with the underlying granodiorite is not evident in the VLF data.
