INTRODUCTION

The 1982 Clair UTEM grid lies about 15 kilometres due west of Kimberley, B.C. Access to this very mountainous area is via the Matthew Creek Road (see Plate 242-83-1). The 1982 work is an extension of the 1981 UTEM work done to the west of St. Mary's Lake (Lajoie, 1982) which was also done on the Clair claims. The whole claim group is known to be underlain by the Proterozoic clastic sediments of the Middle and Lower Aldridge Formation. The sediments of the Aldridge Formation are known to host the Sullivan ore deposit near Kimberley.

The objective of the UTEM survey was to detect electrical anomalies that may be directly or indirectly related to economic mineralization of the Sullivan type.

DESCRIPTION OF THE UTEM SYSTEM

UTEM is an acronym for "University of Toronto Electromagnetometer". The system was developed by Dr. Y. Lamontagne (1975) while he was a graduate student at that University.

The field procedure consists of laying out a large loop of single-strand insulated wire and energizing it with a transmitter powered by a motor generator. The loop is generally square shaped, wherever possible, with sides between 500 metres and 1,500 metres long. In this survey, the loop dimensions were approximately 1,500 x 1,000 metres. Survey lines are located outside the loop and are generally oriented perpendicular to the side of the loop. The field procedure is very similar to Turam, a better known electromagnetic surveying method.

The transmitter loop is energized with a triangular current at a carefully controlled frequency (30.974 Hz for this survey). The receiver consists of one sensor coil, associated electronics, and a facility for digital recording on a cassette magnetic tape. The time synchronization between transmitter and receiver is achieved through quartz crystal clocks in both units.

The receiver sensor coil measures the vertical component of the magnetic field and it responds to the time derivative of the magnetic field. Since the transmitter current waveform is triangular, the receiver coil will sense a perfect square wave in the absence of geologic conductors. Deviations from a perfect wave are caused by electrical conductors which may be geologic or cultural in origin.

The UTEM receiver gathers and records nine channels of data at each station. The later number channels (7-8-9) correspond to short time or high frequency while the lower numbered channels (1-2-3) correspond to long time or low frequency. Therefore, poor or weak conductors will respond on channels 9, 8, 7 and 6. Progressively better conductors will give responses on progressively lower number channels as well. For example, massive, highly conducting sulphides or graphite will produce a response on all nine channels.

It was mentioned above that the UTEM receiver records data digitally on a cassette. This tape is played back into a minicomputer at the base camp. The minicomputer processes the data and controls the plotting on a small (11" x 15") graphics plotter. Data are portrayed as profiles of each of the nine channels, shown for each survey line of each transmitter loop. These profiles, and an interpretive plan are appended to this report.

FIELD WORK

A field report including personnel is included in Appendix I. In total, approximately 45 kilometres of readings were taken, with a station spacing of 50 metres. In addition to the vertical field measurements, horizontal fields were also measured on several lines. All of this surveying took place between August 22nd and October 4th, 1982.

The main problem in this survey was the extremely rough terrain and poor access to some areas of the grid which slowed down the rate of production significantly.

DATA PRESENTATION

The results of the survey are presented in the UTEM compilation map, Plate 242-83-2, and 59 Data Sections (D.S.) in Appendix III. There is also a location and claim map, Plate 242-83-1. The grid is in the metric system. Therefore, L4000N, 2000E means Line 4000 metres north and Station 2000 metres east.

In order to reduce the field data, the theoretical primary field of the loop must be computed at each station. The normalization of the data is as follows:-

1. Continuously normalized plots

a) For channel 1:

$$\% \text{ Ch.1 anomaly} = \frac{\text{Ch.1} - P}{P} \times 100\%$$

where P is the primary field from the loop at the station and Ch.1 is the observed amplitude of Channel 1

b) For remaining channels (n = 2 to 9)

$$\% \text{ Ch.n anomaly} = \frac{(\text{Ch.n} - \text{Ch.1})}{\text{Ch.1}} \times 100\%$$

where Ch.n is the observed amplitude of Channels n (2 to 9)

2. Point normalized plots

These plots display an arrow at the top of the section indicating the station to which all data on the line are normalized. The purpose of point normalized plots is to display only the relative amplitude variation of the secondary field along the line, that is, only that magnetic field from the induced currents in the ground.

a) For channel 1

$$\% \text{ Ch.1 anomaly} = \frac{\text{Ch.1} - P}{P_A} \times 100\%$$

where P_A is the primary field from the loop at station 'A' and Ch.1 is the observed amplitude for Channel 1.

b) For the remaining channels (n = 2 to 9)

$$\% \text{ Ch.n anomaly} = \frac{\text{Ch.n} - \text{Ch.1}}{\text{Ch.1}_A} \times 100\%$$

where Ch.n is the observed amplitude of Channel.n and Ch.1_A is the above reduced Ch.1 anomaly at station 'A'.

Point normalized plots are usually produced on data sections with anomalies to help in interpretation.

The above normalization procedures result in chaining errors displayed in Channel 1 only.

Topography is plotted alongside the Channel 1 data.

DISCUSSION OF DATA

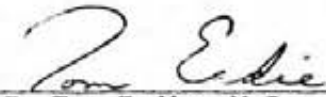

An examination of the Data Sections in Appendix III and the compilation map, Plate 242-83-2 shows that there are a total of 17 crossover type anomalies on the grid. About half of these anomalies are uninteresting single line conductors that probably indicate the presence of either a small fault zone or a small amount of unusually conductive overburden or host rock.

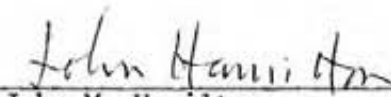

However, most of the better anomalies continue from one line to the next. Three of these features with some strike length have been outlined on Plate 242-83-2. The most interesting of these is Zone A, which has a strike length of at least 1,500 metres.

Zone B is a feature that appears to be very similar to Zone A. Perhaps it is a faulted extension of the first zone. Zone C is a very weak zone and is probably related to a fault.

CONCLUSIONS

Two zones of possible interest were detailed during the 1982 Clair UTEM survey. They are similar to each other in anomaly shape and may be related to each other. Zone A, the stronger of the two zones, should be detailed with more UTEM work.

UTEM COMPILATION MAPS

Axis of a crossover anomaly. The number indicates the latest anomalous channel.

Depth indicated by: S - Shallow ($< 30m$)
M - Moderate (30-60m)
D - Deep ($> 60m$)

Axis of reversed crossover anomaly produced when a small conductor dips at less than 70° towards the transmitter. In normal crossover the positive response is towards the transmitter; reversed one, it is away from the transmitter.

Indicates a negative anomaly of width shown by the dash. The latest anomalous channel is shown. Can sometimes be confused with the negative part of a crossover anomaly.

Outline of a transmitter loop.

Conductor axis located by crossover anomalies with a conductance determination. The conductance is the interpreted conductivity x thickness of the conductor in mhos (same as Siemens).

Only the principal crossovers are indicated.
