LIST OF FIGURES

LIST OF TABLES

1. SUMMARY

Nine diamond drill holes, totalling over 880 m, were completed during July - August, 1983, on the LS #1 and AB #3 and #4 claims, Horsefly area. Placer Development acquired the property in 1983 through options and staking.

Two previously drilled holes (74-01 and 74-02) intersected low gold and copper values and upon completion of geological mapping, geochemical and geophysical surveys by Placer in May 1983, diamond drilling was initiated to test the area near these 1974 drill holes. Core from both the 1974 and 1983 drilling was geologged on site and the 1983 core split, sampled on 3 m intervals, and assayed for gold, silver, copper, and arsenic.

A bedded sequence of fine to coarse pyroclastic and volcanic sedimentary rocks was encountered in the drilling.Rock types include volcanic, hypabyssal, and mixed breccias, tuffs and crystal lapilli tuffs of possible dacitic composition, and volcanic grits, sandstones, and siltstones. The sequence strikes ENE and dips 30° N, with apparent offsets due to shearing and faulting. Patchy to pervasive alteration gives the rocks a bleached appearance, especially in and near fault zones. Main alteration minerals include carbonate, quartz, sericite, epidote, and some clay. Veining is extensive throughout parts of the sequence, but generally only the quartz ± carbonate veinlets carry chalcopyrite. Gold is believed to occur as tiny blebs within the chalcopyrite.

The best gold and copper values occur in parts of diamond drill holes 74-01 and -02, and 83-04 ,-06, and, -07. The mineralized zone appears to strike northeasterly and dip roughly 60° to the southeast. It is believed to be cut off by inferred faulting to the northeast, but is quite possibly open to the southwest.

2. STATEMENT OF EXPENDITURES

The expenditures listed below were incurred for a diamond drilling program on the Horsefly property located approximately 9 kms south of the village of Horsefly, B.C. in the Cariboo Mining District. The 883.25 m of drilling was done on the LS #1 and the AB #3 and #4 claims during the period of July 22 to August 3, 1983.

(1)	**Diamond Drilling** Olympic Drilling and Consulting Ltd.	$53,268.
(2)	**Transportation** 2 trucks @ $30./truck/day x 16 days	960.
(3)	**Assaying *** 187 samples x $30. per sample	5,610.
(4)	**Bulldozer** - 57 hours @ $55./hr	3,135.
(5)	**Motel**	1,004.
(6)	**Meals** - 48 person days	755.
(7)	**Labour ****	12,750.
(8)	**Report Preparation** - 15 days x $225./day ...	3,375.
		$80,857.

W. Pentland	- Senior Geologist - 22 days @ $250./day	$ 5,500.
S. Campbell	- Research/Project Geologist - 18 days @ $225./day	4,050.
P. Pacor	- Geologist - 16 days @ $200/day	3,200.

3. INTRODUCTION

During the period July 22 to August 3, 1983 a diamond drilling program was carried out on the LS #1 and the AB #3 and #4 claims on the Horsefly property located 9 kms south of Horsefly, B.C. (see Figures 1 and 2). A total of 883.25 m of NQWL size was drilled in 9 holes from 8 drill sites. The contractor was Olympic Drilling and Consulting Limited of Richmond, B.C.

Access to the property is by gravel road from Horsefly to both the west and east sides of the property with a narrow dirt road extending through the area of the drilling.

Placer Development Limited became interested in the area early in 1983 and acquired the property through options and staking. The interest was aroused by low gold and copper values found in two holes drilled on the property in 1974.

In May, 1983 a program of geological mapping, geophysics and soil sampling was completed on the property. The core from the present drilling was logged and split in 3 meter intervals with one half being shipped to the Placer Development Limited laboratory in Vancouver where it was assayed for gold, silver, copper and arsenic. The remaining half of the core is presently stored in Horsefly.

4. PROPERTY GEOLOGY

Outcrop on the Horsefly property is largely restricted to the southeastern corner of the Megabuck claim and the southwestern sector of the MB #3 claim. Isolated outcrops occur to the northwest, in the vicinity of Initial Posts for the AB #3 and #4 claims, and on the southern side of Deerhorn Lake. While the outcrop distribution is poor, it is sufficient to permit the partial outlining of formations as indicated by Map 3-1961 (Geology - Quesnel Lake, G.S.C. 1961) (See Figure 3) when used in conjunction with the magnetic data.

The oldest rock on the property is a hornblende granodiorite of Jurassic and/or Cretaceous age exposed along the southern boundary of the MB #3 claim (Figure 4). The magnetics and distribution of boulders indicate that this intrusive underlies the eastern side of the MB #3 claim with a possible extension to the northwestward into the MB #2 claim.

CENOZOIC

QUATERNARY
PLEISTOCENE AND RECENT

22 — Glacial deposits and recent alluvium; till, gravel, sand, silt, and clay; few if any bedrock exposures

TERTIARY AND QUATERNARY
PLEISTOCENE AND EARLIER

21 — Basaltic breccia and tuff; minor flows

TERTIARY
MIOCENE AND/OR LATER

20 — Basaltic flows; minor tuff, conglomerate, and sandstone

PALEOCENE (?) TO MIOCENE (?)

19 — Sandstone, shale, and tuff

PALEOCENE AND/OR EOCENE

18 — Brown and buff rusty weathering dacite and rhyolite

MESOZOIC

JURASSIC AND/OR CRETACEOUS AND (?) EARLIER

17 — 17a, hornblende-biotite and biotite-quartz monzonite and granodiorite, minor hornblende-biotite syenite and monzonite; 17b, hornblende-biotite syenite and monzonite; 17c, hornblende diorite; 17d, muscovite granite and quartz monzonite including pegmatite; 17e, gneissose biotite granodiorite, altered and gneissose diorite, and augen granite (part of unit 17e may be Palaeozoic); 17f, trachyte porphyry (may be volcanic); 17g, green andesite and fine-grained diorite (may be volcanic)

JURASSIC (?) AND CRETACEOUS (?)
MIDDLE JURASSIC (?) TO CRETACEOUS (?)

16 — Green andesitic tuff, agglomerate, and flows; minor argillite, chert, and conglomerate

JURASSIC
MIDDLE (?) AND/OR UPPER (?) JURASSIC

15 — Dark green pyroxene-bearing andesitic agglomerate, breccia, and flows; minor tuff; may be equivalent to unit 14

14 — Green pyroxene-bearing andesitic agglomerate, breccia, and flows; minor tuff, argillite, and limestone; may be equivalent to unit 15

LOWER JURASSIC (?)

13 — Purplish brown, brown, and grey pebble and cobble conglomerate and sandstone; soft, friable, black and brown, carbonaceous shale, green shale; minor black limestone

LOWER JURASSIC

12 — 'Purple' volcanic rocks; purplish brown, dark grey, and rarely green pyroxene-bearing andesitic agglomerate, breccia, and flow; may contain analcite near contacts with units 10 and 11; minor limestone, argillite, and conglomerate

TRIASSIC AND/OR JURASSIC
UPPER TRIASSIC AND/OR LOWER JURASSIC
(may include MIDDLE JURASSIC)

11 — Green pyroxene bearing andesitic flows, agglomerate, and breccia; conglomerate, argillite, and limestone

TRIASSIC
UPPER TRIASSIC

10 — 10a, green and purplish brown pebble and cobble conglomerate and sandstone; 10b, green andesitic volcanic rocks, andesitic feldspar porphyry, argillite, limestone, and pebble conglomerate

The remainder of the rocks on the claims are apparently of Tertiary age. All appear of volcanic origin or as derivatives of volcanics. The formation has been sub-divided into two zones with the first and probably oldest rocks lying immediately to the west of the granodiorite. These rocks are tuffs with grey to greyish green hornblende and feldspar crystal tuffs predominating. Lesser amounts of dark, fine grained ash tuffs were also noted.

Many of the beds are magnetic carrying up to 3% magnetite. Mapping and the magnetic survey indicate a general northerly strike to a zone roughly 500 meters wide extending northward from the claim boundary for at least 1000 meters.

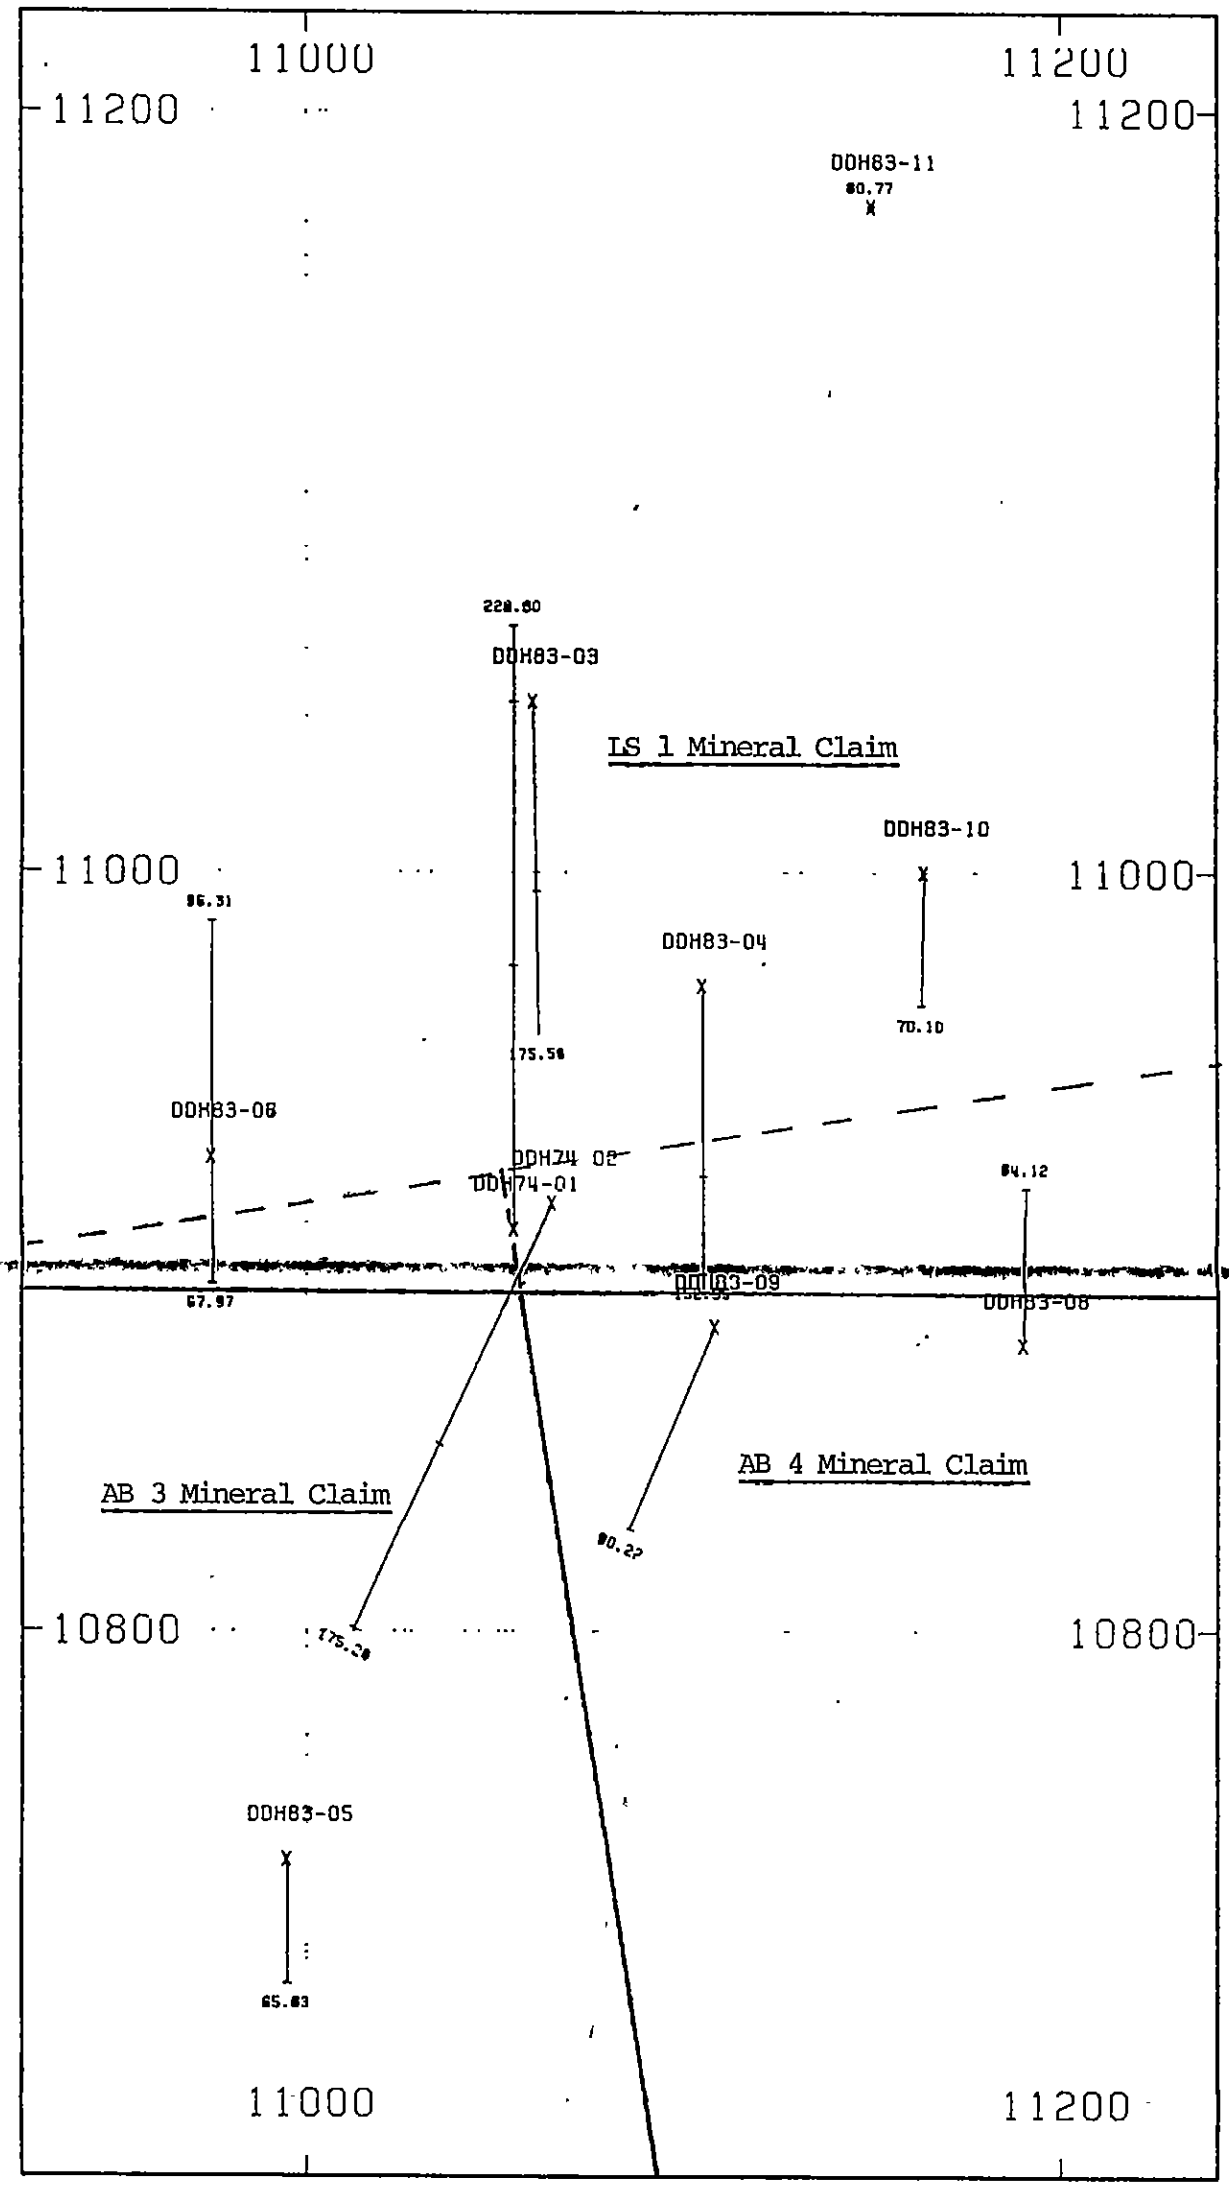
Beyond the zone of crystal tuffs to the west and northwest the outcrops are composed of volcanic breccias and sandstones with the latter believed of tuffaceous origin. Clasts in the breccias are angular to rounded and up to boulder size with the majority being 1 to 4 cm. in diameter. Clast composition is variable but the majority are crystal tuffs similar to and probably originating from the rocks bordering the intrusive to the east.

Lying to the northeast and south of the breccias are fine to coarse grained impure sandstones. These may possibly be reworked tuffs. The few bedding attitudes noted were rougly east-west with a moderate northerly dip. Most outcrops of both the breccias and sandstones exhibit weak to strong epidote alteration.

5. DIAMOND DRILLING RESULTS

5.1 General Statement

The present drilling program was done to gain some appreciation of the low grade copper-gold mineralization found in holes 74-01 and 02. The drilling was centered at 10+950 N and 11+050 E on the grid which is approximately 200 m southwest of the south end of Deerhorn Lake (Figure 5). The area is bounded to the east by a creek draining into the lake. The forest cover is fairly open being a mixture of poplar, cottonwood, lodgepole pine, spruce and fir.



PLACER DEVELOPMENT LIMITED

"GEOLOG" SYSTEM:

PROJECT NAME: HORSEFLY LOCATION MAP
DDH LOCATION PLAN

FIGURE 5.

PLOTTED ON: 83-09-07 SCALE 1:2000 (METRES)

Only two outcrops occur in the area. Holes 74-01 and 02 were collared in poorly exposed volcanic breccia while a coarse volcanic grit is exposed 150 m to the north. The latter is bedded at approximately 260°/30° N. Overburden in the area is extensive and believed particularly deep to the westward.

The area is marked by a cluster of magnetic highs and lows and is bounded to the east and west by north-south striking VLF-EM linears. It is also located on the southern edge of a large induced polarization anomaly outlined in 1973-74.

5.2 Rock Types

Both the 1974 drill holes (74-01 and 74-02), which were relogged, and the 1983 drill holes were logged on site using GEOLOG. Lithologies encountered in the drilling program include fine to coarse pyroclastic volcanic rocks and their reworked equivalents (volcanic sediments). They are further subdivided on the basis of types of fragments. These rocks are bedded, showing a similar attitude to that of the exposed volcanic grit. Details of each rock unit are given below. Cross sections are presented in Figures 6, 7, 8 and 9. Drill logs are contained in Appendix 2.

HYVL: HYPABYSSAL - VOLCANIC BRECCIA

This is a coarse pyroclastic rock composed of subangular, small to large lapilli-sized fragments of rock types that appear to be hypabyssal or sub-volcanic in nature. Fragments amount to 30 to 50 percent by volume and are generally seriate porphyritic to sub-granular and feldspar-rich. Finer-grained, more definite volcanic fragments, such as feldspar porphyry with an aphanitic groundmass, may also be present, but generally amount to much less than 10 percent by volume. Pinkish feldspar is quite typical in both fragments and matrix of this rock unit. The matrix is commonly fine- to medium-grained and similar in appearance to some of the rock fragments.

HVVL: HYPABYSSAL-VOLCANIC TO STRICTLY VOLCANIC BREECIA

This coarse pyroclastic rock is basically a mixed breccia, midway between the above unit and the volcanic breccia unit mentioned below. It consists of subrounded to subangular, small to large lapilli-size

fragments, roughly equally split between sub-volcanic, which generally tend to be larger in size, and volcanic rock types. Fragments make up 10 to 50 percent by volume and include seriate porphyritic feldspar-rich rock (possibly syenitic to monzonitic in composition), fine-grained intermediate to mafic volcanic flows (and possibly tuffs), and considerable feldspar porphyry with a dark greenish-grey very fine-grained groundmass. This rock unit may contain interbedded sections of thinly bedded tuff.

VOLC: VOLCANIC BRECCIA

This rock is a medium to dark greyish-green coarse pyroclastic composed of subangular fragments of volcanic rock with generally less than 10 percent by volume hypabyssal or sub-volcanic material fragments. Although fragments vary in size from small to large lapilli, they are typically smaller on average than those in the hypabyssal-volcanic breccia. Rock types forming the fragments include fine-grained intermediate to mafic volcanics, rhyodacite, and feldspar porphyry, with the majority of fragments appearing to be andesitic in composition. This volcanic breccia contains 25 to 70 percent by volume rock plus some crystal fragments. The matrix is generally fine-grained and a darker greenish-grey. As with the other coarse pyroclastics, this volcanic breccia locally shows interbeds from one to a few centimeters thick, of alternating coarser and finer-grained tuffaceous material.

TFXL: CRYSTAL LAPILLI TUFF

This greenish-grey pyroclastic varies from a coarser-grained tuff with a few lapilli fragments to a more definite crystal - rock lapilli tuff. The unit varies from massive to well bedded with finer and coarser-grained fractions in alternating laminae. Rock fragments are subrounded to subangular and typically small lapilli, but ranging up to large lapilli in size. Rock types forming the fragments include porphyritic dacite, andesite, and feldspar porphyry. Crystal fragments are mostly plagioclase and hornblende with possibly some pyroxene. Rock fragments form 5 to 20 percent by volume of this crystal lapilli tuff and fragments locally show a crude orientation subparallel to bedding. The matrix is typically fine-grained. Overall composition of this pyroclastic unit appears to be quartz latitic to dacitic.

TUFF: TUFF

This unit is a moderately dark greyish-green, fine- to medium-grained tuff that varies from well bedded to massive. Grain size in individual laminae is generally uniform. Typically crystal and rock fragments are absent or amount to not more than 2 to 3 percent by volume. Intercalations of a paler green finer ash tuff occur locally. This tuff appears to be largely dacitic in composition.

VLGT: VOLCANIC GRIT

This is the coarsest of the reworked volcanics or volcanic sedimentary rocks. It is generally bedded to more massive, medium-grained, has a very "grainy" texture, and contains 5 to 25 percent clasts. The clasts are subrounded, medium to large pebble size, and include andesite, feldspar porphyry, very fine-grained intermediate to mafic volcanic rock, some hypabyssal material, and minor small clasts of quartz. Locally, clasts are elongate subparallel to bedding.

VLSN: VOLCANIC SANDSTONE

This greenish-grey reworked material contains fine to medium sand sized particles. It is commonly massive, but locally shows good bedding. A few coarser, more gritty beds alternate with finer-grained layers. The volcanic sandstone shows some bands of spotty magnetite running nearly parallel to bedding.

VLSI: VOLCANIC SILTSTONE

This unit is the finest-grained of the reworked volcanic material. It is generally medium brownish- to greenish-grey, well bedded, and locally contains intercalated sandy and gritty laminae. In some sections it is difficult to determine with certainty whether the rock is truly a volcanic sitlstone or whether it is just a fine ash tuff.

LATI: LATITE

This is a very restricted unit, occurring over a 2 meter section in DDH 83-08 (see Figure 9). It is pale greyish and porphyritic with an aphanitic to very fine-grained groundmass. Phenocrysts are medium-grained and include feldspar, some hornblende, and minor quartz. This porphyritic latite is bounded on either side by faults.

BRAI: INTRUSIVE BRECCIA

This rock appears to be rhyolitic and consists of pale green to off-white, subangular, acidic fragments in an aphanitic, darker green to greenish-grey matrix. It is intrusive, showing sharp contacts and "fingers" penetrating country rock, both of which are oriented at high angles to bedding. This intrusive breccia occurs only in DDH 83-04 (see Figure 8). Shearing and brecciation in the vicinity of this unit have taken place later. Also, later veining and alteration are spatially associated with the intrusive breccia. These will be discussed in section 5.4.

5.3 Structure

Examination of diamond drill core indicates that the above coarse to fine pyroclastic rocks and their reworked or sedimentary equivalents form a layered sequence having an attitude compatible with that measured on the volcanic grit exposed near the collar of DDH 83-03. Attempts at correlating between holes are hampered by shearing and faulting. Also, the core shows variable volumes of some units interbedded with others and correlation in areas where faults are absent requires a certain amount of transition from one unit to another. The layered sequence varies from dominantly tuff, crystal lapilli tuff, and volcanic breccia in the lower part to dominantly volcanic grit at the top. The central part shows a mixture of reworked volcanics along with minor crystal lapilli tuff and volcanic breccia, changing upwards to more mixed and hypabyssal breccia.

This shallow northerly dipping sequence is variably, but consistently fractured with micro- to small mega-fractures. The majority of fractures are about equally divided between steep (90^{o} to 60^{o} dip) and moderate (60^{o} to 30^{o} dip), with relatively few shallow angle fractures. Best fractured units are the volcanic breccia (VOLC), hypabyssal-volcanic breccia (HYVL), and the volcanic siltstone (VLSI). Fractures are also moderately abundant in the volcanic grit (VLGT) and volcanic sandstone (VLSN).

Shearing and faulting occur throughout the layered sequence. A bleaching effect due to pervasive alteration is present within and peripheral to the fault zones. This will be discussed in Section 5.4. One

major fault persists through diamond drill holes 74-01, 74-02, and 83-04 (see Figure 7 and 8). The faulted zone is about 17 m wide, strikes 026° and dips 59° SE. Surface trace of this fault coincides roughly with one of the interpreted VLF-EM anomalies (see Figure 10). Faulting is extensive throughout DDH 83-07, but the attitude of faulting relative to bedding was not determinable. Although DDH 83-06 and 83-07 were both drilled on the same site, but in opposite directions, there is absolutely no correlation between rock units. This, plus the faulted nature of most of the drill core from DDH 83-07, suggests that the hole was drilled along a major fault or such that it cuts the fault at a fairly shallow angle. An interpreted VLF-EM anomaly, which probably represented this fault, strikes 031° and passes through the site where both DDH 83-06 and 83-07 were collared. If DDH 83-07 was drilled essentially parallel through the fault, then true dip of the fault would be 72° SE.

Diamond drill holes 83-08 and 83-10 consist of volcanic breccia, crystal lapilli tuff, and tuff. This appears to be the lower part of the section, suggesting that uplift has occurred and the area is structurally separate from the area drilled to the west. Indeed, two interpreted VLF-EM anomalies appear to define the east and west boundaries of this apparently uplifted block.

5.4 Alteration

Rock units encountered in the drill core show various types and degrees of alteration. Rock forming minerals, such as feldspar and mafics, have been altered to epidote and chlorite, respectively. Magnetite-hematite aggregates, 2 to 3 mm across, appear to be a relatively late feature, occurring throughout the drill core. These aggregates are typically disseminated in certain sections of the core and some bands of spotty magnetite-hematite run nearly parallel to bedding in the volcanic sandstone (VLSN). The aggregates are especially concentrated in areas of pervasive epidote and in some lapilli fragments. In DDH 83-11 sections of core with abundant magnetite aggregates appear to alternate with sections showing disseminated pyrite. Usually a transition zone, 10 to 30 cm wide, marks the boundary between alternating sections. Within this zone, aggregates contain both magnetite and pyrite in varying proportions and it appears that the pyrite is forming from magnetite, but this is not conclusive.

PROJECT NAME: HORSEFLY LOCATION MAP

DDH LOCATION PLAN

LEGEND

INTERPRETED VLF-EM ANOMALY

INTERPRETED IP ANOMALY

FIGURE 10.

PLOTTED ON: 83-09-07 SCALE 1:2000 (METRES)

Significant bleaching of rock units occurs in and around fault zones. Minerals, such as carbonate, sericite, clay, some chlorite, epidote, and hematite are present in fault gouge and as pervasive alteration on either side of the fault. This pervasive carbonate $\pm$ sericite $\pm$ clay $\pm$ quartz is what gives the rock a bleached appearance. Between fault zones, rock units are generally well veined and show numerous open space fillings of quartz and carbonate. Some shearing and faulting is after at least some of the quartz veining, as fragments of quartz veinlets occur within the gouge. These quartz fragments are not chalcopyrite-bearing.

Patchy to pervasive alteration is also present in some sections of core away from fault zones. Patches of epidote, quartz-carbonate as open-space fillings, and (amethyst) quartz with K-feldspar, carbonate, and pyrite were noted. Epidotized lapilli fragments may have bleached haloes in the matrix around them. This feature is generally found near a fault zone. Pervasive alteration minerals include carbonate and, to a lesser extent, hematite.

Stringers, veinlets, and a few larger sized veins are typical throughout the layered sequence. Veining occurs both parallel to bedding and at high angles to it. One very common vein set runs nearly parallel to the core axis of 83-04, which would mean the veins dip anywhere from 60° to 90° and could have any possible strike direction. Another common vein set is present at 50° to 70° to the core axis of DDH 83-04. Veinlets occur most commonly as scattered fracture fillings, but also in local stockworks. Stockwork veining is most typically quartz-carbonate or chlorite. Ribbon texture in some individual veinlets suggests more than one stage of fracture filling. Larger veins, 5 mm wide or wider, show zoning with a central zone of epidote and minor carbonate and an outer zone of quartz. Some of these veins contain minor chalcopyrite in the quartz zone. The following is a list of typical mineral associations found in the stringers and veinlets:

(1) quartz-carbonate: the most common mineral association; locally with envelope of epidote

(2) quartz-carbonate-chalcopyrite: with patchy K-feldspar envelope; believed to be carrying the gold

(3) quartz-carbonate ± hematite ± pyrite

(4) quartz-epidote

(5) epidote: with K-feldspar envelope

(6) epidote ± carbonate ± hematite

(7) carbonate ± sericite ± chlorite

(8) carbonate ± pyrite ± hematite: carbonate - pyrite veinlets may show bleached envelope of carbonate + sericite; carbonate-hematite stringers are present in some fault zones

(9) hematite ± pyrite

K-feldspar envelope are preferentially associated with quartz- rather than carbonate-bearing veinlets. In some cases sericitization is pervasive along veinlet walls. Two relative age determinations were possible for the veinlets:

(1) some carbonate stringers cut quartz-epidote veinlets; and

(2) some carbonate-sericite veinlets cut quartz ± chalcopyrite veinlets.

As mentioned in Section 4.2, extensive alteration and veining is associated with the intrusive breccia unit (BRAI) found in DDH 83-04. Patchy alteration includes K-feldspar, epidote, and some pyrite. Open spaces in the intrusive breccia have been filled by carbonate ± quartz ± hematite ± pyrite ± chalcopyrite. The breccia is bounded on either side by quartz veinlets carrying some hematite and minor chalcopyrite. These veinlets post-dated intrusion of the breccia.

5.5 Mineralization

Sulphides present within the area drilled include pyrite, chalcopyrite, and very rarely pyrrhotite. Pyrite is the most abundant sulphide, especially in diamond drill holes 83-05, 83-08, and 83-11. It occurs as disseminations and in veinlets. Disseminated pyrite is found in both matrix and fragments of the coarse pyroclastics. Some epidotized

fragments in the crystal lapilli tuff and volcanic breccia units have central patches of pyrite, suggesting that pyrite crystallized from the iron-rich volcanic fragments when exposed to introduced sulphur. In general, pyrite disseminations may vary locally to larger blebs and patches. In some of the volcanic siltstone pyrite disseminations are strung out parallel to bedding. In DDH 83-11 sections of the core with abundant disseminated magnetite (- hematite) alternate with sections rich in pyrite. Generally, a narrow zone marks the transition from one to the other and is marked by disseminated aggregates of magnetite and pyrite together in various proportions. Megascopically it appears that pyrite is forming from the magnetite.

Chalcopyrite occurs in a variety of veinlets and to a lesser extent as disseminations. This disseminated chalcopyrite may well be related to very tiny microfractures. One hematite stringer shows an envelope zoned outward from carbonate-sericite to K-feldspar and containing disseminated chalcopyrite. Stringers and veinlets containing chalcopyrite may occur individually, in subparallel groups, in small scale stockworks, or in horsetailing patterns. Most commonly chalcopyrite is associated with quartz veinlets, which run parallel to or within 30° to the core axis of DDH 83-04. Other attitudes are also present, but far less abundant. Minor chlorite, epidote, and carbonate may be associated with these chalcopyrite-bearing quartz stringers. A few larger veins, containing quartz-carbonate-sericite±hematite, also carry chalcopyrite and run nearly parallel to the core axis of DDH 83-04. One large vein of quartz-carbonate-epidote-chlorite+minor chalcopyrite, shows subordinate stringers of quartz-carbonate-chalcopyrite branching out from it. Chalcopyrite occurs in a few epidote stringers and some carbonate-hematite±epidote± magnetite stringers, which run nearly parallel to the core axis of DDH 83-04. Age relationships of the different veins are generally obscure, but in one part of DDH 83-04, a carbonate-quartz-hematite veinlet at 55° to the core axis cuts and offsets quartz-chalcopyrite stringers.

Chalcopyrite is also found in and around fault zones. Some quartz veinlets on either side of faults carry minor chalcopyrite. A section of heavy faulting in DDH 83-04 contains stringers and veinlets of hematite-magnetite+very minor chalcopyrite and less abundant fracture fillings of carbonate-quartz, some of which cut the former.

Chalcopyrite occurs very locally in DDH 83-11. In a section of drill core from 25 to 30 m chalcopyrite is present as 1 to 5 mm blebs in quartz-carbonate±sericite veins and rarely as large "gobs" measuring .3 to 2 cm across. Also of note in DDH 83-11, are large veins, 1 to 1.5 cm wide, of specular hematite-chlorite-carbonate-pyrite±sericite.

Visible gold was not encountered in any of the drill core, however it is believed to be associated with chalcopyrite in quartz veins, most probably occurring as microscopic blebs within the chalcopyrite. Mineralographic work on concentrate from a metallurgical test run by Placer's Research Centre earlier in 1983 revealed some chalcopyrite grains with included micron-size blebs of gold. Also, the best gold values show good correlation with sections of the core containing numerous chalcopyrite-bearing quartz veinlets.

6. DISCUSSION OF RESULTS

Two surface outcrops occur on the property in the area drilled; one a massive volcanic breccia, the other a bedded volcanic grit unit with attitude 260°/30°N. Diamond drill holes from 1974 and 1983 show the continuation of these units at depth and indicate that the thickest section of volcanic grit overlies both volcanic and other breccias and finer-grained pyroclastics and volcanic sediments. The entire sequence of rock units is bedded with an attitude comparable to that measured on the volcanic grit outcrop.

Faulting has affected the layered sequence, restricting correlation between drill holes. Many of the faults encountered in the drill core can be correlated with interpreted VLF-EM anomalies. The overall effect of faulting has produced a few "blocks" that have moved predominantly up and down relative to each other. For example, a fault runs through between DDH 83-06 and 83-07, in cross section probably following the attitude of DDH 83-07 very closely. Volcanic grit south of this fault appears to have been downdropped relative to rock units encountered north of the fault trace. Rocks present in DDH 83-08 and 83-10 appear to be lower in the sequence than units at comparable elevations to the west. These two drill holes are situated in what appears to be a fault-bounded "block" that has been pushed up relative to the "block" on the west side.

Patchy to pervasive alteration, imparting a bleached appearance to various rock units, appears to be the product of hydrothermal activity that used the faults and large shear zones as channelways. The most common alteration minerals are carbonate, clay, and sericite with varying amounts of other minerals such as quartz, epidote, chlorite, and K-feldspar. Dominant vein minerals are carbonate and quartz, whereas subordinate constituents include epidote, chlorite, hematite, and K-feldspar. One gets the impression that more than one alteration front has passed through the layered sequence, but age relationships are not clear. Two relative age determinations from cross-cutting veinlets show that at least some carbonate post-dates some of the quartz and epidote. Source of the hydrothermal activity is unknown.

The apparent replacement of disseminated magnetite by pyrite and the occurrence of pyrite as patches in the centers of epidotized volcanic fragments suggests that sulphur was introduced to the system ie. there was an increase in sulphur fugacity at some point during hydrothermal activity. This introduced sulphur is also depicted by chalcopyrite-bearing quartz veinlets and by pyrite stringers, and disseminated chalcopyrite and pyrite.

Although gold was not observed in any of the drill core, four factors provide evidence for the interpretation that gold occurs as micron blebs within chalcopyrite only: (1) gold and copper assays show good positive correlation; (2) gold assays are best where chalcopyrite-bearing veinlets are most abundant; (3) gold assays and pyrite content show a negative correlation; and (4) earlier mineralographic work on a metallurgical sample from Horsefly property revealed some chalcopyrite grains with included blebs gold.

Mineralized sections in the drill core show a relatively higher grade zone, averaging about 1.3 g Au/tonne in the central part of the area drilled (see Figure 11) and a lower grade zone, averaging roughly 0.5 to 0.6 g Au/tonne, surrounding it. As the majority of chalcopyrite-bearing quartz veinlets run nearly parallel to or at a shallow angle to the core axis of DDH 83-04, and since the zone is elongate in plan view, it is interpreted as being a flattened cylindrical zone of mineralization plunging roughly 60° or more in the direction 145°. Interpreted faults appear to cut off the zone to the northeast, however to the southwest the zone is open. If indeed the zone continues to the southwest then its geometric shape becomes more planar with a strike of 055° and a dip of roughly 60° or more to the southeast.

GOLD > 1.3 ppm

GOLD > 0.5-0.6 ppm

FIGURE 11.

PLOTTED ON: 83-09-07 SCALE 1:2000 (METRES)

An apparent spatial relationship exists between pyritized rock and the mineralized zone. Disseminated pyrite is most abundant in the bottom of DDH 74-01, and in DDH 83-03, 83-05, 83-08, and 83-11. (Note that DDH 83-11 is within a previously interpreted IP anomaly). This gives somewhat of a pyrite halo to the zone of gold-copper mineralization.

7. CONCLUSIONS

Gold-copper mineralization, related to disseminated chalcopyrite and chalcopyrite-bearing quartz ± carbonate ± epidote veinlets, cross cuts a layered sequence of fine to coarse pyroclastic and volcanic sedimentary rocks. Host rocks are partly carbonatized and propylitized, especially in and near the mineralized zone. Mode of occurrence of this gold-copper mineralization, presence of a partial halo of pyritic rock, and alteration features suggest that we are looking at a porphyry-type occurrence of gold and copper, possibly related to an alkalic intrusive body. Evidence is lacking for the occurrence of an alkalic plug on the property, but then again this zone of mineralization may represent only a "satellite" occurrence related to a larger system in the nearby area.

This is the Upper Tier Geodata Header, consisting of 3 parts -- The bottom part is the Upper Tier Scales(SCL) entry, required for declaring the Unit of Length in (4) = Mt.2 = metres with 2 places of decimals; in (5) are the units used for measuring recovery: could be MT.2. The middle part, Upper Tier Names (NAM) entry, is provided to allow the user to change the name of any field. Eg: to replace galena=GL in (27) with cassiterite=CT, enter CT immediately below GL in the /NAM-entry. Finally, the top part contains the abbreviated names of the 29 fields which will soon become very familiar:(5)=Core Recovery; (6)=Type Modifier; (7)=Percent Mix, using the G-Scale; (8)=Rock Type; (9)=Typifying Minerals 1 & 2;(10)=Qualifying Mineral 1;(11)=Textures 1 & 2;(12)=Grain Sizes -- FF=Fine Fraction, CF=Coarse Frac, %C=Percent Coarse, MP=Max Particle; (13)=Fracture Intensity: FI/s = FI of Steep Fracs, MI=Mineral Intensity of specified mineral or minerals, on all fractures; (14)=Ri=Repeat Interval: enter R if Repeat Interval or P if Principal Geologic Interval or D if Ditto Option or A if As-Above Option (explanation in GEOCODER); (15)=Mode Thickness T_1 of litho-feature indentified in 16 ; (17)&(18)=Strike & Dip to right of planar feature or Strike & Plunge of linear feature, identified in 16 ; (19) to (28) = ten 2-column fields for default suite of alteration & ore-type minerals: quartz(QZ) biotite(BI) clay(CY) carbonates(CB) magnetite(MG) pyrite(PY) chalcopyrite(CP) galena(GL) and any 2 minerals XX & YY, which may differ from interval to interval -- simply enter the 2-letter mineral code (with the How & Amount being entered immediately below in the Lower Tier entry); and (29)=Summary of alteration -- F_A = Alteration Facies, A_I = Alteration Intensity, M_Z = Metal Zone & I = Intensity of Mineralization.

Field Ref # 1 2 3 4 5 6 7 8 9a 9b 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27 28 29

This is the Lower Tier Geodata Header and, like the preceding Upper Tier Header, also consists of 3 parts for the same reasons. Note that MT.2 has been entered in (5) in the LSCL-entry, under RQD=Rock Quality Designation, indicating that if,say,123 is entered in C18-20, the System will read this as 1.23m. The abbreviated Lower Tier Headings are: (5)=RQD, as above; (6)=Age or Formation; (7)=Environment of Emplacement; (8)=Rock-Type Qualifier=RTQ (use Short Form of Rock Type); (9a)=LC=Lightness-Colour Code, (9b)=Typifying Mineral 3, or (9)=LBHU Colour; (10)=Qualifying Mineral 2; (11)=Textures 3 & 4; (12)=Grain Characteristics:S_R=Degree of Sorting, R_N=Roundedness, S_{ll}=Shape or Sphericity & O/C=Open/Closed Structure; (13)=Frac Intensity of Moderate & Low Fractures; (14)=Ri=Repeat Interval, as in 14 above -- enter R or D only if Lower Tier is repeated without the Upper Tier; (15)=Mode Thickness T_2 of litho-feature identified in 16; (17)&(18)=Strike & Dip to right of Structure 2, identified in 16; (19)to(28)= ten 2-column fields for default suite of alteration & ore-type minerals: K-spar(KF) muscovite(MU) chlorite(CL) epidote(EP) hematite(HE), the How & Amount of any mineral XX entered above, pyrrhotite(PR) molybdenite (MO), sphalerite(SL), and the How & Amount of any mineral YY entered above; and (29)=How_1 & How_2 of all alteration minerals and How_1 & How_2 of all ore-type minerals for the interval.

A4. Supplemental Diamond Drilling, December 1983

During the period December 3-8, 1983 an additional 62.5 m of drilling was done in three holes on the Horsefly property. The holes were located to the southwest of the collars for 74-1 and 2 and were drilled to check for a possible extension of the higher grade mineralization, i.e. 1.25 gms Au/tonne. The work was done by Northspan Exploration Limited using a truck mounted drill.

Drilling Results

Hole 83-12 intersected mainly volcanic breccia with short intervals of volcanic grits and sandstones and minor tuff. Gold values were very low.

Hole 83-13 encountered hypabyssal volcanic breccia identical to that found in the top sections of holes 74-1 and 2. The core contained chalcopyrite as disseminations and in the occasional small quartz vein. Gold values were less than 1 gm/tonne.

Hole 83-14, located as a further step-out to the southwest, was abandoned at 19.8 m in overburden.
