DATA SHEETS

LISTING OF PICKED FIDUCIAL POINTS

1. INTRODUCTION

This report contains our interpretation of the results on an INPUT MK VI airborne electromagnetic and magnetic survey flown for Kidd Creek Mines Ltd. The survey area lies within the Province of British Columbia, approximately 10 kilometres east of the Town Duncan on Vancouver Island. The area outline is presented on the following page.

The survey was commissioned by Mr. P. DeLancey of Kidd Creek Mines Ltd. on April 26, 1984. D. Martyn, Geophysicist for Questor supervised the data acquisition and preliminary data reduction while the author completed data compilation through to the completion of the project in July, 1984. Mr. G. Hendrickson of Kidd Creek Mines visited the survey base to review results and production.

The survey objective is the detection and location of base metal sulphide conductors within mostly Paleozoic volcano-sedimentary lithology of the Sicker Group.

The primary survey area consists of 214 kilometres of traverse and control lines. These were flown on June 11 and June 12, 1984 using Duncan as the survey operations base.

2. SURVEY OPERATIONS

2a. Project Location

A Bell 205A Helicopter equipped with the **QUESTOR/BARRINGER** MK VI INPUT system was utilized for the survey, which is composed of 1 contiguous block. The survey area lies at the junction of N.T.S. Maps 92B12 and 13.

2b. Production

The flight line spacing over the block was 200 metres. The table summarizes the kilometres flown during the survey operation.

Traverse lines	212	km.
Control lines	16	km.
Total lines	228	km.

The survey was completed in two production days and three flights. A further flight on June 18 was used to place fill-in lines to span navigation gaps. No production was lost to any cause during the survey.

2c. Survey Personnel

The survey crew was made up of experienced **QUESTOR** and **Trans Canada Helicopter** employees:

- Crew Manager/Geophysicist - D. Martyn
- Pilot/Captain of Helicopter - B. Masson (Trans Canada)
- Co-Pilot/Navigator - B. Smith
- INPUT Equipment Technician - D. Makos
- Aircraft Engineer - J. Caza (Trans Canada)

The flight path recovery was completed at the survey base, while the final data compilation and drafting was carried out by QUESTOR at its Mississauga, Ontario office. The magnetic and electromagnetic processing was carried out using QUESTOR software and computer drafted by DATAPLOTTING SERVICES. The INPUT interpretation and reporting was completed by M.H. Konings, P.Eng.

Mr. Grant Hendrickson, Geophysicist for Kidd Creek Mines was the technical authority for the project. A preliminary compilation of results - a red ball anomaly map - was kept current at the survey base and presented to Kidd Creek Mines at the completion of the field data acquisition.

2d. Data Compilation

The flight path of the aircraft is recorded by a frame camera on black and white 35 mm. film continuously during flight. The camera is controlled by the fiducial time system of the data acquisition system so that pictures are taken once every 2 seconds. Fiducial numbers are imprinted on the film, marked onto the analogue records and recorded digitally at the same instant.

The flight line headings are opposite on adjacent lines, which are normally flown sequentially in an "S" pattern. The navigation references are flight strips at a scale of 1:20,000 which are made from the base maps. The equipment operator logs the flight details recording line numbers, time, the fiducial range and other pertinent flight information. This information comes from the magnetic tape after it has been recorded (read-

after-write). It is compared to the film, analogue records and the magnetic base station recording at the completion of the survey flight.

The film and all records are developed, edited and checked at the completion of each flight. Recovery of the flight track is carried out by comparing the negative of the 35 mm. film to the topographic features of the base map. Coincident features are picked and plotted on exact copies of the stable mosaic base map on which the final results are drafted. Points are picked at an average interval of 1 kilometre. This corresponds to one whole fiducial unit or 20 seconds. The picked points will not necessarily fall on whole fiducial numbers, but on the final presentation, only the first and last whole numbers on a line are marked on each flight line. By interpolation, the whole numbers are marked as ticks along the flight path. This keeps the anomaly and interpretation maps free of unnecessary numbers. The actual location of the picked fiducials is marked on the flight path as a round point, whose fiducial value is summarized at the end of this report.

These procedures are performed daily so that the data quality and progress may be measured objectively. Reflights for covering navigational gaps and other deficiencies are usually flown on the following day.

The analogue records are inspected for coherence with specifications, and anomalies are selected for classification and plotting. Selected anomalous conductors are positioned by

plotting their fiducial positions, less the lag factor (Appendix C). These resultant positions are located by interpolating between fiducial points established by the flight path recovery process.

The survey results are presented as 4 products. There is an INPUT anomaly map with magnetic contours, a magnetic contour overlay with flight lines and an E.M. anomaly map with interpretation.. The summary describes the interpretation of INPUT results and presents recommendations for ground follow-up surveys. In addition, a colour contour map is also provided.

3. INPUT DATA PRESENTATION

The base maps for the survey area are photomosaics constructed from 1:63,350 air photographs supplied by the British Columbia Map Office and taken in 1982. These were used first for the flight strips and later as the base onto which the flight path was recovered. The mosaics are uncontrolled at a scale of 1:10,000. The area was partitioned as illustrated on the location map.

The INPUT anomaly map presents the information extracted from the analogue records. This consists chiefly of the peak anomaly positions and response characteristics, surficial responses, up-dip responses, and magnetic anomaly locations. In effect, these represent the primary data analysis. The symbols are explained in the map legend, but the following observations are presented:

- position of peak anomaly;
- conductance or conductivity-thickness;
- amplitude of channel 2 response;
- channel 2 half amplitude profile width (for amplitudes greater than 75 ppm);
- position and peak amplitude of associated magnetic anomalies;
- where present, surficial, up-dip, poorly defined responses have been identified with a unique symbol.

The INPUT interpretation maps outline the geophysical-geological interpretation of the electromagnetic, magnetic, geological and physiographic data. The primary survey target - bedrock conductors have axis locations and dip directions, where they are interpretable. The anomalous zones which are recommended for follow-up have a reference label assigned, to which additional comments and recommendations are directed in the Interpretation Report, following this section. Surficial response sources are mapped out by boundaries showing their interpreted lateral extent. The following list summarizes the interpretation presentation:

- bedrock conductor axis, probable and possible;
- conductor dip;
- surficial conductor outlines;
- anomalous conductors selected for ground evaluation with reference number.

4. INTERPRETATION - GENERAL

4a. Regional Geology

Saltspring Island is underlain by mostly Paleozoic age volcanic and sedimentary rocks of the Sicker Group. The exposure of these older units in Southern Vancouver Island occurred as a result of an event described as the Cowichan-Horne Lake Uplift. Younger Mesozoic rocks of the Nanaimo Group have been reported to directly overlie rocks of the Sicker Group. These are exposed at the Sansum Narrows and at the southeast corner of the island.

Specifically, the survey area is dominated by the Myra Formation. These are described by J.E. Muller in GSC Paper 79-30 as a thick succession of schistose, folded and deformed rocks. The rocks have apparently been derived from basic to silicic tuff and breccia with some argillite and greywacke.

It has been reported that sills of meta diabase are intercalated with the sediments. On early geological references, the Sicker Group appears to have been mapped as the "Saanich Granodiorite". The Saltspring Intrusive in the northern half of Saltspring Island has been interpreted as the lower level of a volcanic centre in the reference. The economic of the Myra Formation is demonstrated by the Ag, Au, Cu, Pb, Zn and Cd mineralization in the Westmin Deposits, presently being mined.

4b. Conductivity Analysis

The conductivity-thickness products of planar horizontal and thin, steeply dipping conductors are proportional to the time constant of the secondary field electromagnetic transient decay. This transient may be closely approximated by an exponential

function for which the conductivity-thickness product (TCP) is inversely proportional to the log difference of two channel amplitudes at their respective sample times.

These response functions are presented in the form of graphs in which the amplitudes of the 6 channels of INPUT response are plotted on a logarithmic scale against conductivity. The relative amplitudes of the secondary response, at any given conductivity, may be accurately related to the depth of a conductor below the surface. These are typically referred to as Palacky nomograms. These are available for a number of conductor geometries. It has been found that the shape of the decay transient and its amplitude is usually unique to a particular geometry. Therefore, if the origin of a conductive response is in question, a good "fit" of the peak response amplitude to one nomogram will define its origin.

The 90° nomogram was utilized exclusively to determine the apparent conductances of the responses obtained from the survey. This assumption is valid for near vertical conductors, within a dip range of $45-135^{\circ}$, relative to the aircraft flight direction.

Although the conductor depth can be interpreted from the nomograms, the short strike lengths and the variability of conductor geometry may result in the over-estimation of depths. The response shapes are indicative of shallow depth conductors over the entire survey area, with 0-50 metre depths interpreted for most selected zones. The INPUT system depth capability is typically 200 metres for a vertical, 600 metre strike length by 300 metre depth extent target. The effective penetration depth

increases for a dipping target and decreases for a smaller size conductor.

Depths were only determined for responses which appear to fit the interpretation model - a thin near vertical plate with a strike length of greater than 500 metres. Qualifications for these determinations are summarized in the interpretation section.

An anomaly listing at the back of this report summarizes each anomalous response in a numerical sequence. In addition to the standard anomaly parameters, an "anomaly type" classification has been added. The letters correlate with the plotted symbols according to the following table.

<u>ANOMALY TYPE</u>	<u>RESPONSE SOURCE</u>	<u>SYMBOL</u>
BLANK	bedrock conductors	circular
S	surficial (overburden or lakebottom) conductivity	diamond
U	up-dip accessory peak to main response	half circular, half diamond, symbolically "pointing" in dip direction
W	down-dip peak	same as above
P	poorly defined response	asterisk "*" in lower left quadrant
C	cultural source	square

The "P" poorly defined response may not yield signatures diagnostic of a discrete bedrock anomaly to standard electromagnetic prospecting equipment. Interpreted axis locations may be approximate for these intercepts.

5. INPUT INTERPRETATION

Above background electromagnetic responses of the Saltspring Island INPUT survey can be categorized into five classes:

- a) salt water conductivity - Satellite and Sansum Narrows;
- b) geological conductivity enhanced with probable electrolytic solutions (salt water);
- c) cultural responses;
- d) weak geological responses;
- e) bedrock responses.

In addition to the above, a uniform background secondary field was evident over almost all of the survey. This is undoubtedly due to a very weak electrolytic conduction in soils caused by salt on Channels 1 and 2 as a very fast decay, however it is much stronger in the perimeter of the amplitudes of the survey area, close to the water level. The half width amplitudes of channel 1 are very broad and extend well inland for the salt water responses. This can be attributed to higher concentrations of salt caused by wind-borne spray.

This has an additional effect on the conductors in the survey area. Current gathering or the effect of surficial conductivity interacting with a bedrock conductor has probably helped to enhance weak geological conductors, generally causing exaggerated response amplitudes.

5.1 Salt Water Responses

Response 10380A is typical of a salt water response contrasted to generally resistive conditions northward towards

responses B,C and D. The physical model for salt water is a horizontal layer. No shift of the channel peaks should occur, and in the absence of altimeter variations, only a single peak will be registered. Where there is no salt water intrusion, the responses will return to background levels quickly and predictably. The half width limits for horizontal conductors very accurately delineate the extent of the horizontal conductivity.

Salt water responses as a rule occur at the edge of the survey area and as a rule, the peak amplitudes occur further out, past the ends of the flight lines. From responses 10260A and 10380A, the high conductances are characteristic of a salt water response.

5.2 Geological Conductivity

Although the author had only sketchy geological information available, across the northern survey boundary a unit of the Nanaimo group of Mesozoic age sediments is in contact with the Sicker Group. We propose that the southern extent of the conductivity for those horizons marks the contact. The responses are broad and originate from a wide source. To distinguish this unit from adjacent weaker responses, they are represented with the diamond shaped symbols which we normally use with surficial or layer source conductivity.

At least three linear conductive bands can be traced across the northern end of the area. The southern half width limit should be a reliable contact marker between a resistive and

conductive (resistivity low) rock unit. For flight lines directly adjacent to Burgoyne Bay, INPUT responses for this horizon show the effects of salt water intrusion. Both amplitudes and apparent conductances increase to the west from flight line response intercepts 10340D and 10350A. This unit therefore, has both a permeability and porosity increase in contrast to the Sicker group volcanics.

Magnetic contours suggest that this unit has a marginally greater susceptibility with magnetic peaks often coincident with INPUT response peaks.

We suggest that carbonaceous sediments are the explanation for bulk conductivity where salt water intrusion is not a problem. The main evidence for this is the consistency of response shapes, response amplitudes and apparent conductances over very many kilometres.

The interpreted conductor axis represents the central portion of the conductor while the half width limits define the edges.

5.3 Cultural Responses

Where recognized, responses attributed to man made conductive sources are outlined by a black square with lower case letters. These occur between Bruce Peak and Hope Hill and extend downhill (northward) along flight lines 10221 and 10210.

The power line monitor did not respond but the shape of the responses and their positions are exactly coincident with roads. The form of the responses is a double response peak which

fits a vertical to near vertical sheet model. For cultural responses, this is usually produced by a grounded hydro or telephone line, sometimes by a fence but not by a buried pipe.

All of the responses on flight line 10221 between cultural response "A" and geological response "C" are interpreted as cultural conductivity effects, in this case seen as lateral effects from flying offset and near parallel to the source. The same principles probably apply to response 10210D.

The sharpness of ZONE 7A, combined with its location in a clearing, leaves it suspect as a bedrock source, although a film check could not confirm this. Similarly, the sharp consistent and symmetric character of ZONE 37D leaves it suspect; however, as its northern extent lies in bush, away from the potential cultural effects of Musgrave Landing, a bedrock source is possible.

5.4 Weak Geological Responses

With the notable exceptions of ZONES 7A and 37D (discussed on the following section) the southwestern third of the survey area has a resistive character. It is modified by enhanced somewhat by conductive soils; however, up to six horizons of extremely poor responses have been identified. Their generally weak character combined with wide profile widths (rarely depicted by half width presentation due to low amplitudes) leaves the interpreter to believe that these are geological units with a minor conductivity contrast. In spite of what may appear to be local conductivity-thickness anomalies caused by modification by

increasingly conductive soils in the proximity of the southwestern shore, and the author's uncertainty in classifying these responses as definitely geological to possible bedrock, no follow-up recommendations are suggested.

Two origins are possible for these horizons as depicted on the interpretation maps:

- a) carbonaceous conductors;
- b) permeable horizons susceptible to weathering.

The first situation is well understood; however, the second possibility would require detailed mapping to substantiate. We suggest that some of the responses could originate from within tuff horizons, for example, which could be marginally conductive by natural weathering but could also be enhanced by infiltration of natural electrolytic solutions - ground water with salt spray.

The southern third of the survey area is also characterized by flat magnetic gradients. As there are some strike discrepancies between the interpreted axial traces and magnetic contours, comparisons with geological information are recommended to either explain the observation or modify the interpretation.

ANOMALY 1C

Conductance	14S
Dip	?
Strike Length	+ 400 m.
Magnetic Correlation	
Related Responses	10015B, 10021D, 10041D

Where the southwestern 3/4 of the survey block is characterized by a relatively flat magnetic background of 56300 nT, the area of profound formational conductors has a consistently higher background susceptibility. This may have direct relation to the Nanaimo unit. The responses selected appear to lie within this unit if there is a direct geological relation to the weak susceptibility contrast. The INPUT responses can best be described as subtle inflections on the flank of the formational conductors. It is conceivable that both the amplitudes and conductances are enhanced by the superposition of high amplitude formational responses.

The formational conductor to the north appears to dip to the northeast on flight lines 10010S and 10015S while immediately to the south, bedrock conductors dip south with no indication for the 1C response.

The axis location for the selected "anomaly" must be considered approximate; however, the vertical axis peaks should closely approximate a location over the conductive sheet if it is dipping.

ANOMALY 5B

Conductance	13S
Dip	-
Strike Length	-
Magnetic Correlation	-
Related Responses	-

The 10050B intercept is located closely adjacent to the Nanaimo unit formational conductors. The response was selected for its sharp, narrow profile. It is possible that the conductor may extend westward, superimposed on the flanks of the formational zone. The axis position should be considered approximate while its position close to a sharp local magnetic response in an otherwise uniform unit is a favourable situation.

ANOMALY 6C

Conductance Range	6-11S
Dip	S
Strike Length	3 km.
Magnetic Correlation	-
Related Responses	10010DE, 10015C, 10021C, 10030B 10041C, 10050C, 10060E (10065C)

The zone is a consistent long horizon, invarient in amplitude and conductance. The responses, except for 10010D, are up and down dip peaks, interpreted from the shifted peaks. The value of the dips is interpreted to lie between 40 and 60°. The selected response (intercept 10065C) exemplifies the form of the responses. The horizon should be investigated together with ZONE 6D (10060D), as it has no apparent section of enhanced responses.

ANOMALY 6D

Conductance	22S
Dip	S
Strike Length	400 m.
Magnetic Correlation	14 nT
Related Responses	10050D

The 6C ZONE is unique in the survey area because a magnetic anomaly is coincident with the best part of the E.M. responses. Along strike, weak and diffuse responses can be traced along strike to the NE for 2 km.; however, axis positions should only be considered approximate. The half width extent to the southwest gives a better indication of the lateral extent of the conductor, which at best is still weak and diffuse. The low amplitudes are evidence of a non-massive source of the conductivity while the "22" Siemen value presented may be somewhat artificial due to superposition with the adjacent conductive horizon to the north.

The dip of the conductor is southwest at a flat to moderate value. This is deduced by the shift of later time channel peaks in the direction of dip.

A high priority ground follow-up is recommended for this zone, utilizing techniques sensitive to poor conductors.

ANOMALY 7A

Conductance	9S
Dip	-
Strike Length	250 m.
Magnetic Correlation	-
Related Responses	10071A

Two unusually sharp responses occur isolated from other conductance trends. The sharpness and single intercept nature of the responses can only be interpreted as a limited dimension horizontal source. The responses occur in a clearing. In ground follow-up, look for a fence with or without a ground, having side lengths of less than 200 x 200 metres.

If culture cannot explain the source, then a horizontal or very flat dipping bedrock source with very limited surface projection dimensions will be the conductivity explanation. The half width shown for the 10071A response graphically presents the approximate width dimension.

ANOMALY 13F

Conductance	8S
Dip	N?
Strike Length	100 m.
Magnetic Correlation	15 NT
Related Responses	-

The 13F response intercept is weak in amplitude; however, the form of the transient suggests that the conductance has been underestimated. The response is directly associated with a local sharp magnetic peak.

The poor amplitudes, combined with the sharp response profile, are not unusual for a source with limited dimensions and this type of response is associated with spheric or system noise characteristics.

The response, in spite of its limited dimensions, should be considered a first priority target.

ANOMALY 37D

Conductance	34S
Dip	90°
Strike Length	+ 1,100 m.
Magnetic Correlation	-
Related Responses	10331DE, 10340AB, 10351BC, 10360AB, 10365AB, 10371C

All of ZONE 37D responses are typical of a vertical sheet target. The higher amplitudes of the western intercepts (ie, 10331E, 10340A) relative to their matching responses on the opposite side of the conductor axis can be attributed to superposition of background resistivity low responses. The exceptional consistency of the response shapes and amplitudes is often a sign of culture. Although the responses do trend through some open areas near Musgrave Landing, they also extend northward into an area of thick bush.

If the zone has a cultural source then the low amplitudes would be attributed to a vertical ribbon type conductor. No depth interpretation was attempted for this zone as the low amplitudes would cause an overestimate of depth for a conductor whose shape is characteristic of a shallow source.

6. CONCLUSIONS AND RECOMMENDATIONS

Although surficial conductivity is present in the survey area, it is homogenous in nature and does not severely interfere with the INPUT interpretations with the exception of the presented half width extent. These may be locally overestimated, especially in coastal areas to the southwest.

Formational conductors, with the exception of the strong zone along the northeast survey boundary, may be supplemented with representative sections of the weaker horizons and the "isolated" responses which occur randomly throughout the project area, for which no axis interpretation has been made. The model targets for the survey - the Westmin Deposits - are not noted for electrical characteristics, especially when depths are well below the ground surface and the target size is finite.

Respectfully submitted,

QUESTOR SURVEYS LIMITED

Marcel H. Konings, P.Eng.,

Senior Geophysicist.

APPENDIX ABARRINGER/QUESTOR MARK VI INPUT^(R) Helicopter System

The INDUCED Pulse Transient (INPUT) method is a system whereby measurements are made, in the time domain, of a secondary electromagnetic field while the primary field is between pulses. Currents are induced into the ground by means of a pulsed primary electromagnetic field which is generated from a transmitting loop around the helicopter. By using half-sine wave current pulses (Figure A-1) and a transmitter loop of large turns-area, a high signal-to-noise ratio and the high output power needed for deep penetration, are achieved.

Induced current in a conductor produces a secondary electromagnetic field which is detected and measured after the termination of each primary pulse. Detection of the secondary field is accomplished by means of a receiving coil, wound on an air core form, mounted in a PCV plastic shell called a "bird" and towed behind and below the helicopter on 76 metres (250 feet) of coaxial cable. The received signal is processed and recorded by equipment within the helicopter.

The axis of the receiving coil may be vertical or horizontal relative to the flight direction. In rolling or hilly terrain the standard or horizontal coil axis is preferred, although in steep terrain, the vertical axis coil optimizes coupling with horizontal or dipping stratigraphy. The secondary field is in the form of a decaying voltage transient, measured in time, at the termination of the primary transmitted pulse. The amplitude of the transient is proportional to the amount of

measured in time, at the termination of the primary transmitted pulse. The amplitude of the transient is proportional to the amount of current induced into the conductor, the conductor dimensions, conductivity and the depth beneath the aircraft.

The rate of decay of the transient is inversely proportional to conductance. By sampling the decay curve at six different time intervals and recording the amplitude of each sample, an estimate of the relative conductance can be obtained. Transients due to strong conductors such as sulphides and graphite, usually exhibit long decay curves and are therefore commonly recorded on all six channels. Sheet-like surface conductive materials, on the other hand, have short decay curves and will normally only show a response in the first two or three channels.

For homogeneous conditions, the transient decay will be exponential and the time constant of decay is equal to the time difference at two successive sampling points divided by the log ratio of the amplitudes at this point.

TRANSMITTER SPECIFICATIONS

Pulse Repetition Rate	180	per sec
Pulse	Half sine	
Pulse Width	2.0	millisec

SONOTEK P.M.H. 5010 PROTON MAGNETOMETER

The airborne magnetometer is a proton free precession sensor, which operates on the principle of nuclear magnetic resonance to produce a measurement of the total magnetic intensity. It has a sensitivity of 1 gamma and an operating range of 20,000 gammas to 100,000 gammas. The sensor is a solenoid type, oriented to optimize results in a low ambient magnetic field. The sensor housing is mounted on the tip of the nose boom supporting the INPUT transmitter cable loop. A 3-term compensating coil and perma-alloy strips are adjusted to counteract the effects of permanent and induced magnetic fields in the aircraft.

Because of the high intensity electromagnetic field produced by the INPUT transmitter, the magnetometer and INPUT results are sampled on a time-share basis. The magnetometer head is energized while the transmitter is on, but a measurement is only obtained during a short period when the transmitter is off. Using this technique, the sensor head is energized for 0.80 seconds and subsequently the precession frequency is recorded and converted to gammas during the following 0.20 seconds when no current pulses are induced into the transmitter coil.

APPENDIX BThe Survey Helicopter

Figure B1

Manufacturer	Bell Helicopter Company
Type	205A-1
Canadian Registration	C-GLMC - present installation
Date of INPUT Installation	May 1982

Modifications:

- 1) Cradle and wing booms for transmitter coil mounting
- 2) Camera and altimeter mounting
- 3) Modified gasoline driven generator system

Any BELL 205-212 airframe can support the QUESTOR Helicopter INPUT system. The 205 is powered by one low maintenance turbine engine. The configuration of the helicopter provides for easy installation of equipment, which can be disassembled and crated to the survey base. Reassembly takes less than two days. These factors have proven the helicopter to be a reliable and efficient geophysical survey system in areas not suitable for fixed-wing operation.

APPENDIX CINPUT System Characteristics

a) Geometry

The INPUT system, a time domain airborne electromagnetic system, has the transmitter loop located around the helicopter airframe while the receiver, referred to as the 'bird', typically is towed 19 metres behind and 73 metres below the helicopter at a survey airspeed of 40 knots. The actual spatial position of the bird is dependent on the airspeed of the survey helicopter, as can be seen in Figure C1.

Figure C1

b) The Lag Factor

The bird's spatial position along with the time constant of the system introduces a lag factor (Figure C2) or shift of the response past the actual conductor axis in the direction of the flight line. This is due to fiducial markers being generated and imprinted on the film in real time and then merged with E.M. data which has been delayed due to the two aforementioned parameters. This lag factor necessitates that the receiver response be normalized back to the helicopter's position for the map compilation process. The lag factor can be calculated by considering it in terms of time, plus the elapsed distance of the proposed shift and is given by:

$$\text{Lag (seconds)} = \text{time constant} + \frac{\text{bird lag (metres)}}{\text{ground speed (metres/sec)}}$$

Figure C2

The time constant introduces a 1.3 second lag while, at an aircraft velocity of 40 kt., the 'bird' lag is 1 second. The total lag factor which is to be applied to the INPUT E.M. data at 40 kts. is 2.3 seconds. It must be noted that these two parameters vary within a small range dependent on the helicopter velocity, though they are applied as constants for consistency. As such, the removal of this lag factor will not necessarily position the anomalies in a straight line over the real conductor axis. The offset of a conductor response peak is a function of the system and conductor geometry as well as conductivity.

The magnetic data has a 1.0 second lag factor introduced relative to the real time fiducial positions. This factor is software controlled with the magnetic value recorded relative to the leading edge (left end) of each step 'bar', for both the fine and coarse scales. For example, a magnetic value positioned at fiducial 10.00 on the records would be shifted to fiducial 9.95 along the flight path.

A lag factor of 2 seconds (0.1 fiducial) is introduced to correct 50-60 Hz monitor for the effects of bird position and signal processing. In cases where a 50-60 Hz signal is induced in along formational conductor, a 50-60 Hz secondary electromagnetic transient may be detected as much as 5 km. from the direct source over the conductive horizon.

The altimeter data has no lag introduced as it is recorded in real time relative to the fiducial markings.

c) Calibration

The major advance made during the transition from the INPUT MK V to the INPUT MK VI has been the ability to calibrate the equipment accurately and consistently. Field tests at established test sites are carried out on an average of once every 6 months to check the consistency of the INPUT installations available from QUESTOR.

To calibrate the equipment for a survey operation the following tests are used:

- 1) "ZERO" the digital and record background E.M. levels;
- 2) magnetometer scale calibrations;
- 3) altimeter calibration;
- 4) calibration of INPUT receiver gain;
- 5) aircraft compensation;
- 6) record background E.M. levels at 600 m.;
- 7) survey flight;
- 8) record background E.M. levels at 600 m.
- 9) record full scale INPUT receiver gain;
- 10) record compensation drift;
- 11) terminate or repeat from step 4.

This sequence of tests may be repeated in midflight given that the duration of the flight is sufficiently long. Typically, this process is conducted every 2 hours of actual flying time and at the termination of every flight.

The background levels are recorded and then used to determine the drift that may occur in the E.M. channels during the progression of a survey flight. If drift has occurred, the

E.M. channels are brought back to a levelled position by use of the linear interpolation technique during the data processing.

The primary electromagnetic field generated by the INPUT system induces eddy currents in the frame of the helicopter. This spurious secondary field is a significant source of noise which needs to be taken account of before every survey flight is initiated.

Compensation is the technique by which the effects of this spurious secondary field are eliminated. A reference signal, which is equal in amplitude and waveform but opposite in polarity, is obtained from the primary field voltage in the receiver coil and applied to each channel of the receiver. The compensation signal is not a constant value due to coupling differences induced by 'bird' motion relative to the aircraft. The signal applied is proportional to the inverse cube of the distance between the 'bird' and aircraft. Figure C3 displays the effect of compensation.

Typically, channel 5 is selected for compensation because it is not affected by geological noise due to its sampling location in the transient and then coupling changes are induced by precipitating 'bird' motion. Phase considerations of channel 5, relative to the remaining channels, dictates whether sufficient compensation has been applied. If the remaining channels are in-phase to channel 5 during this procedure, an over-compensated situation is indicated, whereas, out-of-phase would be indicative of an under-compensation case. Normally this adjustment is carried out at an altitude of 600 metres in

order to eliminate the influence of external geological and cultural conductors.

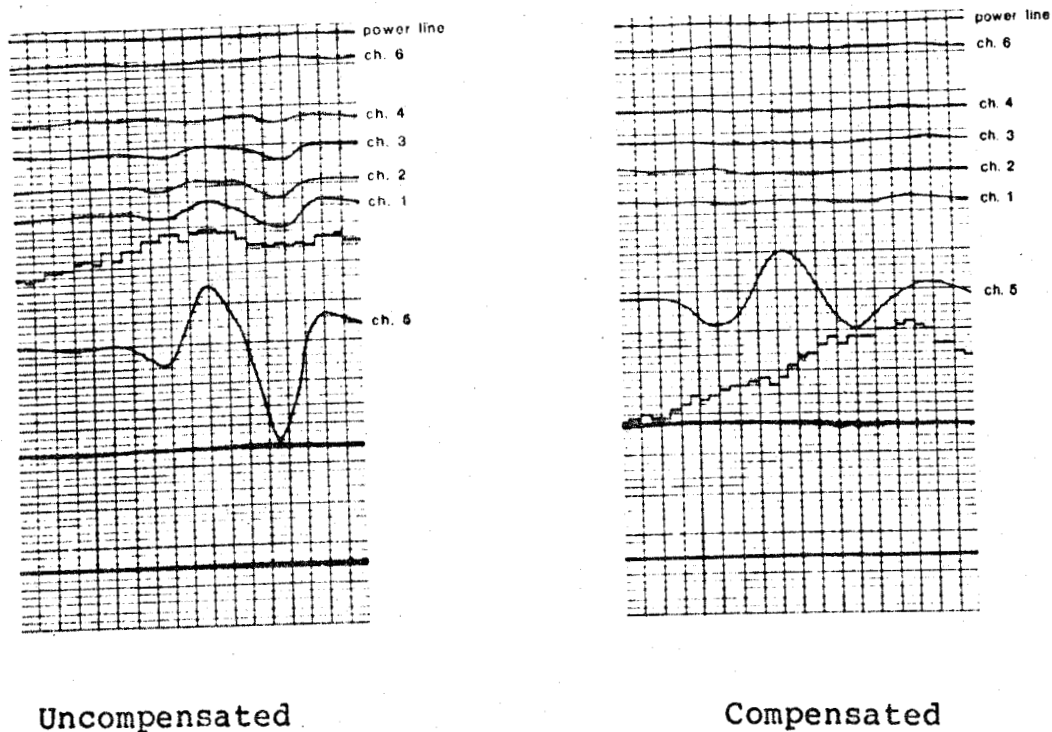

Figure C3

The magnetometer, altimeter and INPUT receiver gain are also calibrated at the initiation of every survey flight. With the magnetometer, there are two scales, a coarse and a fine scale. The fine scale indicates a 10 gamma change for a 1 cm. change in amplitude (Figure C2). The coarse scale moves 2 mm. (or 1 division) for a 100 gamma change with full scale, 2 cm., indicating a 1000 gamma shift.

The altimeter (Figure C4), is calibrated to indicate 400 feet altitude at the seventh major division (7 cm.), read from the bottom of the analog record. This is the nominal flying

height of INPUT surveys, wherever relief and aircraft performance are not limiting factors. The eighth major division correlates with 300 feet while the sixth corresponds with 500 feet in altitude.

Figure C4

The INPUT receiver gain is expressed in parts per million of the primary field amplitude at the receiver coil. At the 'bird', the primary field strength is 8.5 and 8 volts peak-to-peak, for the vertical and horizontal axis coils respectively or 4.2 and 4.0 volts peak amplitude. The calibration signal introduced at the input stage of the receiver is 4.0 mV. Expressed in parts-per-million, this induces a change of:

$$\frac{4 \times 10^{-3} \times 10^6}{4.2} = 1,000 \text{ ppm (vertical coil)}$$

These calibration signals (Figure C5) cause an 8 cm. deflection of all 6 traces which translates to a sensitivity of 125 ppm/cm. for the vertical axis receiver coil system.

Figure C5

With the chart speed increased from the normal 0.25 cm. to 2.5 cm. per second, the time constant of the system (Figure C6), can be obtained by analysis of the exponential rise of the calibration signal for all 6 traces. The time constant, is defined as the time for the calibrated voltage to build up or decay to 63.2% of its final or initial value. A longer time constant reduces background noise but also has the effect of reducing the amplitude of the signal, especially for near surface responses.

Figure C6

This trade-off indicates the importance of selecting an optimum value for the time constant. Experience and years of testing have indicated that a time constant of 1.3 second does not impede interpretation of bedrock source conductors.

d) Depth Penetration Capabilities

There are many factors which effect the depth of penetration. These factors consist of:

- 1) altitude of the helicopter above the ground;
- 2) conductivity contrast between conductor and host rock;
- 3) size and attitude of conductor;
- 4) type and conductivity of overburden present.

Of these factors, only the first parameter can be controlled. Typically, a survey altitude of 120 metres (400 feet) or less above the terrain is maintained. At this height, the helicopter INPUT MARK VI system has responded to conductors located at a depth of 200 metres (650 feet) below the surface.

APPENDIX DINPUT Data Processing

The QUESTOR designed and implemented computer software routines for automatic interactive compilation and presentation, may be applied to all QUESTOR INPUT Systems. The software is compatible with the fixed-wing MARK VI INPUT, and the helicopter MARK VI INPUT. The procedures are all common, however, separate subroutines are accessed which contain the unique parameters to each system. Although many of the routines are standard data manipulations such as error detection, editing and levelling, several innovative routines are also optionally available for the reduction of INPUT data. The flow chart on the following page (Figure D1) illustrates some of the possibilities. Software and procedures are constantly under review to take advantage of new developments and to solve interpretational problems.

a) INPUT Data Entry and Verification

During the data entry stage, the digital data range is compared to the analog records and film. The raw data may be viewed on a high-resolution video graphics screen at any desirable scale. This technique is especially helpful in the identification of background level drift and instrument problems.

b) Levelling Electromagnetic Data

Instrument drift, recognized by viewing compressed data from several hours of survey flying, is corrected by an

interactive levelling program. Although only two or three calibration sequences are normally recorded, the QUESTOR technique permits the use of multiple non-anomalous background recordings to divide a possible problematic situation into segments. All 6 INPUT channels are levelled simultaneously, yet independently. The sensitivity of the levelling process is normally better than 10 ppm on data with a peak-to-peak noise level of 30 ppm.

c) Data Enhancement

Normal INPUT processing does not include the filtering of electromagnetic data. The residual high frequency variations often apparent on analog INPUT data, is due almost wholly to "spherics", atmospheric static discharges. In conductive environments, spherics are apparently grounded and effectively filtered. In resistive environments, frequency spectrum analysis and subsequent FFT (Fast Fourier Transform) filters have been applied to data to reduce the noise envelope.

d) Selection of EM Anomalies

The levelled data may be viewed sequentially on a graphics screen for the selection of INPUT anomalies. Anomalies are selected by aligning a cursor to the position of the peaks. Some of the parameters of the response are manually entered during the picking of the response. These include the number of channels above background levels and the type of anomaly, e.g. cultural, bedrock, surficial, up-dip, etc.

APPENDIX EINPUT INTERPRETATION PROCEDURES

The INPUT system is dependent upon a definite resistivity contrast and is most suitable for highly conductive massive sulphides. Differentiation is possible between flat-lying surficial conductors and bedrock conductors.

The selection of anomalies is based on their characteristics and interpretation is sometimes enhanced by analyzing the magnetics. Spherics, due to atmospheric static discharges and lightning storms, are distinguishable from conductive anomalies. In the analysis of each conductor anomaly, the following parameters may be considered: anomaly shape with the conductor pattern, topography, corresponding magnetic features, anomaly decay rate, the number of channels affected, geological environment and strike direction and the interpreted dip relative to structural features.

For each anomaly selected, the following are recorded: location by fiducial, channel amplitudes in parts per million, number of channels, conductivity-thickness in siemens, corresponding magnetic association in gammas, magnetic fiducial location altitude of aircraft above ground in metres and also, the origin of the response (ie. surficial, bedrock, cultural).

Conductive responses are categorized into three main groups. These are bedrock, surficial and cultural.

Bedrock conductors can be sorted into conductive sources which are commonly encountered on INPUT surveys: massive

sulphides, graphites, serpentized peridotites and fault or shear zones. Magnetite and manganese concentrations may also yield INPUT responses in some circumstances. INPUT responses over alkalic intrusives and weathered basic volcanics have been well documented by Macnae (1979) and Palacky (1979).

Massive Sulphides

Massive sulphides occur as both syngenetic and stratified deposits and as vein infilling deposits. Nickel deposits often occur as magmatic injections of massive sulphides. Kuroko-type syngenetic copper-zinc massive sulphides usually occur at an interface of felsic intermediate rocks. In this environment, there are seldom any significant formations of carbonaceous sediments on the same horizon. Often, these deposits are overlain by a silicious zone which may contain stringers of continuous sulphides, which change to disseminated sulphides away from the main deposit. These often give a deposit the appearance of a long strike-length zone which may not fit the explorationist's target model. A careful analysis of conductivities and apparent widths (half-peak-width), will often reveal the geometry and source. Syngenetic deposits of base metal sulphides of up to 2 km strike length are not unknown, although most sizeable deposits have strike lengths between 500 and 1000 m.

The conductivity of most massive sulphide deposits may be attributed to the pyrrhotite and chalcopyrite content, as both minerals form elongated interconnected masses which are most

amenable to the induction of electromagnetic secondary fields. Pyrite normally forms cubic crystals which must be interconnected electrically in order to produce a response. Massive pyrite often produces only a moderate response which may be difficult to distinguish from graphite. The in-situ conductivity of massive sulphides, although very high for individual crystals, often falls in the range of 5 to 20 S/m.

Sulphide conductive zones are rare in nature; economic sulphides are even more scarce. Long formational sulphide zones are known, but are not common. More often, sulphide concentrations may occur within formational graphitic zones.

The geometry of many syngenetic and injected sulphide deposits may fall within broad classifications of size, conductivity and magnetization but most of these bodies are anomalous within their local geological environment. There are often changes in dip, conductivity, thickness and magnetization with respect to the regional environment. There are no rules which apply universally to massive sulphide deposits. One observation which has consistently applied to sulphide deposits is that INPUT responses (amplitude and conductivity) are roughly proportional to mineral content.

The INPUT system is capable of detecting disseminated sulphides within zones of resistivity changes. These may have low conductivities and responses will normally be restricted to channels 1 through 4. The response amplitudes will vary with the horizontal and vertical extent of the zone. Gold deposits often fall within this response classification.

The magnetic response of a sulphide deposit is the most deceiving information available to the explorationist. Although many large economic deposits have a strong direct magnetic association, some of the largest base metal deposits have no magnetic association. An isolated magnetic anomaly caused by oxidation conditions at a volcanic vent flanking a conductor, may have more significance than a body which has a uniform magnetic anomaly along its strike length. Differing geochemical environments often results in the zoning of minerals so that non-homogeneous conductivities and magnetic responses may be favourable parameters.

Graphitic Carbonaceous Conductors

Carbonaceous sediments are usually found within the sedimentary facies of Precambrian and Proterozoic greenstone belts. These represent a low energy, sedimentary environment with good bedding planes and little or no structural deformation. Graphites are often located in basins of the sub-aqueous environment, producing the same body shape as sulphide concentrations. Most often however, they form long, homogeneous planar sequences. These may have thicknesses from a metre to hundreds of metres. The recognition of graphites in this setting is normally straightforward.

Conductivities and apparent widths may be very consistent along strike. Strike lengths of tens of kilometres are common for individual horizons.

The conductivity of a graphite unit is a function of two variables:

- a) the quality and quantity of the graphite and
- b) the presence of pyrrhotite as an accessory conductive mineral

Pyrite is the most common sulphide mineral which occurs within carbonaceous beds. It does not contribute significantly to the overall conductivity as it will normally be found as disseminated crystals. Greenschist facies metamorphism will often be sufficient to convert carbonaceous sediments to graphitic beds. Likewise, pyrite will often be transformed to pyrrhotite.

Without pyrrhotite, most graphitic conductors have less than 20 S conductivity-thickness value as detected by the INPUT system or 1 to 10 S/m conductivity from ground geophysical measurements. With pyrrhotite content, there may be little difference from sulphide conductors.

It is not unusual to find local concentrations of sulphides within graphitic sediments. These may be recognized by local increases in apparent width, conductivity or as a conductor offset from the main linear trends.

Graphite has also been noted in fault and shear zones which may cross geological formations at oblique angles.

Serpentinized Peridotites

Serpentinized peridotites are very distinguishable from other anomalies. Their conductivity is low and is caused partially by magnetite. They have a fast decay rates, large amplitudes and strong magnetic correlation.

Magnetite

INPUT anomalies over massive magnetites correlate to the total Fe content. Below 25-30% Fe, little or no response is obtained. However, as the Fe percentage increases, strong anomalies result with a distinguished rate of decay that usually is more pronounced than those for massive sulphides.

Contact zones are often predicted when anomaly trends coincide with lines of maximum gradient along a flanking magnetic anomaly.

Surficial Conductors

Surficial conductors are characterized by fast decay rates and usually have a conductivity-thickness of 1-5 siemens. These values will be much higher in saline conditions. Overburden responses are broad, more so than bedrock conductors. Anomalies due to surficial conductivity are not dependent on flight direction. In profile form, surficial responses are symmetrical from line-to-line with the Helicopter INPUT system, and are characterized by a single response rather than a double peak for dipping and vertical conductors. Conductive deposits such as clay beds, may lie in valleys which can be checked on the altimeter trace and with the base maps topography.

Cultural Conductors

Cultural conductors are identifiable by examining the power line monitor and the film to locate railway tracks, power lines, buidings, fences or pipe lines. Power lines produce INPUT

anomalies of high conductivity that are similar to bedrock responses. The strength of cultural anomalies is dependent on the grounding of the source. INPUT anomalies usually lag the power line monitor by 1 second, which should be consistent from line-to-line. If this distance between the INPUT response and the power line monitor differs between lines, then there is the possibility of an additional conductor present. The amplitude and conductivity-thickness of anomalies should be relatively consistent from line-to-line.

Vertical Axis Receiver Dip Interpretation Graph

APPENDIX FINPUT Response Models

To the interpreter, one of the main advantages of the INPUT system geometry is the variation of the secondary response with conductor shape, size, depth and conductivity (Palacky 1976, 1977).

When we discuss the recognition parameters, one of the variables which is often omitted, is the plotting position of the main peaks in opposite flight directions on adjacent lines. In many cases, the responses may appear similar, but the plotting positions will show significant differences. These situations will be illustrated in the following section.

A third conductor identification factor is the INPUT decay transient for the main response peak. The decays may be used to identify the type of source, independent of the geometrical response which is dependent on the mutual coupling.

Model and Physical Conductors

Economic conductive mineral deposits have no unique feature which would make their identification a straightforward process. Most ore bodies do have conductivity contrasts and at least one dimension which is significantly small. A conductivity contrast is necessary to overcome the "skin depth" attenuation effects of conductive overburden or lateritic soils on the primary electromagnetic field (West and Macnae 1982). The recognition of dipping conductors is possible, mainly due to the double peaks encountered in an updip flight direction (Figure F1). A horizontal

mineral deposit is potentially the most difficult to select because the horizontal sheet model also applies to conductive overburden and lateritic soils. The theoretical shapes may be matched to physical-geological situations as has been done in the following summary:

a) THIN DIPPING SHEET OR PLATE:

- economic - stratiform tabular ore body, dyke, vein, fault, fracture mineralization;
- non economic - graphitic-carbonaceous shales, barren sulphides
- cultural - some grounded power lines, fences

b) SPHERE - CYLINDER:

- economic - compact massive orebody; horizontal pipe-shaped conductor
- cultural - some pipelines

c) HORIZONTAL SHEET:

- economic - some stratabound massive sulphides
- non economic - overburden, lateritic soils
 - weathered rock
 - sea water or saline formations
 - graphitic metasediments

d) VERTICAL STRIP (RIBBON)

economic

and

non economic - rarely encountered in nature

cultural - grounded hydro lines, lightning arrestor lines,
fences

e) HORIZONTAL STRIP (RIBBON)

economic - some stratabound massive sulphides

non economic - some syngenetic mineral deposits

geological - weathering of narrow basic rock units with a high
amphibolite content

cultural - grounded and interconnected fences, pipes

THE THIN DIPPING PLATE RESPONSE

ANOMALY MAP PRESENTATION

The interpreted conductor axis location varies with the source dip, conductivity, depth, thickness, depth extent and angle of intersection of the flight line to the conductor (strike direction).

THE SPHERE OR CYLINDER RESPONSE

ANOMALY MAP PRESENTATION

The response of a cylinder may be quite difficult to recognize from a thin strip. A cylinder or spherical model does not show a pronounced negative or upward peak following the main response. Due to the effect of the time constant of the INPUT receiver, the negative peaks which follow the theoretical response do not appear on the INPUT records (Mallick 1972, Morrison et al 1973). As the illustrations show, the sphere-cylinder response is perfectly symmetrical, but not centered over the body. The plotting position of the main peak leads the actual axis location because the most favourable mutual coupling occurs just before the transmitter coil passes the conductive body. The amplitude of the responses will be similar in both flight directions for a perfect cylinder.

THE HORIZONTAL SHEET

ANOMALY MAP PRESENTATION

The horizontal conducting sheet has many variations but it is essentially simple to recognize. The amplitudes of the earlier channels may reach 30,000 ppm where saline solutions are present, however, horizontal sheet responses of channels 4, 5 and 6 attenuate, much faster than for a vertical or steeply dipping plate.

The edge effect is a common interpretational problem where the conductive layer has low resistivities. A secondary peak may occur as the receiver coil crosses the far sheet edge. These responses are always very sharp and often have very high apparent conductivities.

The edges of the sheet are positioned approximately at the half-peak width positions which are usually the inflection points of the profile.

The variations in plotting positions observed for dipping sheets are not as evident for the plate.

It is not unusual to see a shift in the peaks, with the latter channels migrating towards a section of improved conductance and/or increasing thickness. Another characteristic of poorly conducting sheets which respond only on channels 1 through 4 is the inversion of responses on channels 5 and 6. This is a reaction of the compensation circuits to changes in the primary field in the presence of a strong conductor and it serves no practical end except as a recognition aid.

The horizontal sheet model also applies to residual soils or laterite as well as conducting rock units. As the thin overburden situation changes to a thick overburden or two layer case and finally to a half space or a uniformly conductive earth, the responses also vary. The latter cases will have progressively broader responses which would seldom be mistaken for true discrete conductive zones.

When flight lines in opposite directions cross a conductive sheet, an asymmetric mirror image response occurs when the sheet is uniform. If there are variations in the geometry or conductance across the sheet, it may be necessary to compare responses with a shallow dipping sheet conductor to determine the effects, which would not be similar when compared with adjacent lines.

THE HORIZONTAL STRIP (RIBBON) RESPONSE

ANOMALY MAP PRESENTATION

The plotting positions of the responses could easily be mistaken for a vertical plate conductor, however, careful consideration must be given to the line direction. The horizontal ribbon is a degeneration of the horizontal conducting sheet. It can be easily distinguished from a sphere or cylindrical body by its peak asymmetry, whereas the sphere model has a single symmetric main response.

THE VERTICAL STRIP (RIBBON) RESPONSE

ANOMALY MAP PRESENTATION

Due to the fact that this type of response is most commonly caused by fences, lightning protection lines and grounded power lines, the customary cultural presentation is a square symbol. This cultural response symbol may or may not have a power monitor (50-60 cycle) response but these will normally follow pipelines, fences, power lines, roads, railroads and other man made structures. The amplitude and apparent conductivity of such responses varies with the ground conductivity. In residual soils or conductive overburden, it is often possible to see a positive (up-dip type) peak followed by a small negative immediately before the main conductive response. The presence and amplitudes of such responses is normally very consistent. The cause of such responses is interpreted to be current gathering within the surficial sediments (West and Macnae 1982).

APPENDIX G

Quantitative Interpretation

The quantitative interpretation of the INPUT data is normally accomplished by comparing the resultant responses with type curves obtained from theoretical calculations, scale model studies and actual field measurements. A variety of results are available in literature for different conductor geometries and system configurations (see Ghosh 1972, Palacky 1974, Becker et al., 1972, Lodha 1977, Ramani 1980). They also examined the effects of varying such parameters as conductance, conductor depth, dip and depth extent. Their approach has been successfully applied in interpretation of past field surveys.

The nomograms which are currently available for the INPUT system are the Vertical Half-Plane, Homogeneous Half-Space, Thin Overburden and 135 Dipping Half-Plane nomograms. The first is particularly useful for the interpretation of vertical dyke-like conductors frequently found in the Precambrian Shield type environments. In the case of a thick, homogeneous, flat-lying (less than 30 dip) source, the Homogeneous Half-Space nomogram should be applied. While in a thin overburden or tropically weathered rock environment, the Thin Overburden nomogram may be referenced to determine the depth and conductance of the overburden (Palacky and Kadkaru, 1979).

As an example, INPUT anomalies due to vertical dyke-like conductors, are asymmetric and independent of the flight direction. Their shape is characterized by a minor first peak and a major

second peak and their channel amplitudes are a function of the conductivity-thickness product and depth of the source. Anomaly A in Figure G1 illustrates one of these responses.

The channel amplitudes of anomaly A can be used in quantitative interpretation in the following way. Their values are plotted for each of the six channels on logarithmic (5 cycles K+E 46 6213) tracing paper in a straight line using the vertical logarithmic scale in parts per million as given on the right side of Figure G2. The six channel amplitudes for anomaly A, in ppm, are 840, 540, 390, 280, 180, 120, respectively. The amplitudes are measured in ppm (1mm = 30 ppm) from the flight records with reference to the normal background levels on respective channels. Those responses which are not at least three channels or whose first channel amplitude is less than 2 mm or 60 ppm over the normal background should be discarded in the present analysis. The six points on the semi-logarithmic paper are then fitted to the curves of the vertical half-plane nomogram (Figure G2) without any rotation. Having accomplished this, the lateral placement of the plot indicates the apparent conductivity-thickness value, in siemens, and the position of the 10,000 ppm line on the logarithmic paper indicates the conductor depth, in metres. In the example shown (Figure G2), the apparent conductivity-thickness value is 31 siemens and the depth is 46 metres.

The asymmetric Tx-Rx configuration is very sensitive to changes of dip, particularly in the case of conductors dipping against the flight direction. In this circumstance, there is a change in the magnitude of the second/first peak ratio for all

Figure G1

G-4
 FIXED WING INPUT
 VERTICAL HALF PLANE
 CONDUCTIVITY / DEPTH NOMOGRAM

Figure G2

Figure G3

channels. The ratio of the amplitudes of the two peaks is a function of dip. The dip should be the first parameter determined in the quantitative interpretation of a dipping conductor. Before the amplitude is further used for an estimate of conductivity-thickness and depth, it must be normalized to a dip of 90° . This correction is performed by means of the Thin Plate Dip Estimation and Amplitude Normalization Graph, Figure G3.

From the graph, it can be seen that a vertical dyke conductor should have a second/first peak ratio of approximately 6, i.e., that the first peak will have 16% of the amplitude of the second peak. In the case of anomaly A, this condition is true. Conversely, should the dyke dip at 60° , the ratio will decrease to 1.0. Thus, the dip of a conductor can be estimated from the peak ratios of channel two by using the graph in Figure G3.

An example of amplitude correction determination is shown in Figure G3. A dipping conductor has an up-dip second-first peak ratio of 1.0 i.e., that the channel amplitudes of the minor first peak and major second peak of channel two are equal. Taking this ratio of 1.0 and applying the graph, we obtain a dip of 60° for the conductor and an amplitude correction of approximately 1.62. Consequently, the correction factor is applied to the six channel amplitudes of the associative down-dip response. This response is then fitted to the vertical half-plane nomogram for the determination of its apparent conductivity-thickness value and depth. It should be mentioned that without the dip correction, the depth would be overestimated.

An alternate method for estimating the dips of longer, tabular conductors, utilizes the peak amplitudes on adjacent lines, see Figure G4. It is especially useful in multiple conductive zones where the up-dip responses may be obscured or yield false values due to the superposition of other nearby anomalies.

Note that the depth determination is made with the assumption that the aircraft is at 120 metres above the ground surface at the time of measurement. If the aircraft is above or below the altitude of 120 metres, the depth determination can be corrected by respectively, subtracting or adding the difference in altitude, within limits.

The homogeneous half-space, thin overburden and the dipping half-plane 135° nomograms are used in the same fashion as that described above for the vertical half-plane.

To estimate the apparent strike length of a conductor, the ends of the conductive trend must be determined. Modelling has shown that the conductor ends are delineated by INPUT responses having channel amplitudes not less than 40% of those typical for the conductor. Responses with less than that of 40% are attributive to lateral coupling effects and are not considered as intercepts of the conductor. This is especially true for conductors of higher conductivity. Subsequently, the strike length of a conductor is equal to the distance between those responses representing the ends of the conductor.

NAME : MARCEL H. KONINGS

OCCUPATION : Senior Geophysicist

EDUCATION : B.A.Sc., Geological Engineering.
University of Toronto, Toronto, Ontario.

PROFESSIONAL AFFILIATIONS : Society of Exploration Geophysicists (SEG)
Canadian Exploration Geophysical Society (KEGS)
Association of Professional Engineers of the Province of Ontario (APEO).

EXPERIENCE : 1980 Questor Surveys Limited.
Senior Geophysicist.
Responsible for supervision, reporting and interpretation of INPUT and magnetometer survey data.

1981-82 Project Manager/Geophysicist
Mexico magnetics/radiometrics project including field operations, data compilation and interpretation.

1982 Project Manager/Geophysicist.
Brazil INPUT surveys. Responsibilities included field operations, data compilation and interpretation at survey locations.

1976 Shell Canada Resources.
Project Geophysicist.
Duties included supervision of EM, IP, gravity and magnetic surveys as well as interpretation. Geophysical surveys and interpretation resulted in the successful drilling of the East Kemptville tin deposit.

1975 Prospection Limited.
Contract Geophysicist.
Based in the Sultanate of Oman.
Responsibilities included evaluation of INPUT survey results, supervision of geophysical field parties and interpretation of ground transient electromagnetics, magnetics and gravity. Two new deposits were delineated.

1975 Crone Geophysics Limited.
Contract Geophysicist.
Responsible for gravity and elevation surveys, data reduction and interpretation.

1974 Amoco Canada Petroleum Co. Ltd.
Project Engineer.
Involved in mineral exploration programs from initial INPUT surveys through drilling. Part of Detour Lake discovery team.

1972 Amoco Canada Petroleum Co. Ltd.
Geological and geophysical surveying.

1971 New Jersey Zinc Exploration Co.
Geophysical Operator.

DESCRIPTIVE NOTES
 The search is covered with the Barringer/Quinn Mk VI INPUT - Airborne E.M. System and the Sonotek PMS 5015 Pulse Processor Magnetometer and Sonotek SDG-2000 Series Data Acquisition System. The INPUT system will respond to conductive near-buried and near-surface horizontal conducting layers in addition to bedrock conductors. Interpretation of conductors is based on the rate of magnetic decay, magnetic signature, and the relationship between magnetic signature and topography.
 Registered Trade Mark of Barringer Research Limited.
