OPERATOR(S): Chapleau Res.
AUTHOR(S): Banting, R.T.
REPORT YEAR: 1988, 265 Pages
GEOLOGICAL SUMMARY:

The claim area is underlain by Precambrian sedimentary rocks of the Kitchener, Creston, and Aldridge Formations. In the Perry Creek area, the Creston and Kitchener Formations predominates, and are lenticular and trend north. They are commonly fault bounded by the Aldridge Formation to the north. Moyie sills are distributed throughout the map area.

APPENDIX II

S U M M A R Y

This report is sumbitted on behalf of Chapleau Resources Ltd. of 2100 - 4th Street North, Cranbrook, B. C. Chapleau Resources Ltd. is presently the recorded owner of mining property in the Slocan and Cranbrook areas.

The Purcell Camp, comprising of 49 mineral claims of 414 units is located in the vicinity of lode gold prospects between Moyie River and Perry Creek. The property is divided into four contiguous blocks, designated as Morgan, Buck I, Buck II and Bar properties.

In 1987, Chapleau Resources Ltd. conducted an exploration program comprising of prospecting, geochemical sampling, trenching and gological survey. Geoichemical analysis on the Morgan and Bar outlined anomolour zones in Gold and Arsenic, while on the buck and Bar properties, stream sediment surveys clearly defined anomolous concentrations of Zinc and Lead as high as 10,000 ppm.
Prospecting located and outlined a stockwork of gold bearing quartz veins yielding assays of .6 oz/ton.

In consideration of the favourable structural and lithological geology of the Purcell Camp, and in recognition of the several anomalous zones, as evidenced from the 1987 field season, a Phase II program is recommended to evaluate the possibility for bulk-tonnage low grade replacement-type Au deposits and sediment-hosted massive sulphide mineralization.

1.0 INTRODUCTION

1.1 Location and Access

The Purcell Camp, comprised of the Morgan, Buck and Bar claims is located approximately 20 km. due west of Cranbrook, British Columbia. It centers on latitude 49 30'N and longitude 116'04'W (see Figure 1 & 2).

There are two means of access to the property: Access to the Perry Creek - Morgan claims is by a good, active, gravelled logging road from the Kimberley - Cranbrook highway, with junction at Wycliffe. From this point, one keeps to the left along Perry Creek for the south block of claims or bear right (Sawmill Creek Road) for the north block The last several miles are 4-wheeled drive only. Access to the Moyie River - Buck and Bar claims is by good, active, gravelled logging road from Highway #3 west with junction at Lumberton. From this point, one keeps to the Lumberton north side of Moyie River for the Buck and Bar claims.

1.2 Physiography

The property is situated west of the Rocky Mountain trench within the Moyie Range of the Purcell Mountains. The highest evelvation in the area is Grassy Mountain at 2491m. Elevations vary between 1220m and 2130m.

Precipitation is high (80-180cm) compared to other surrounding areas, while snow is considered moderate. Mean temperature compares to Kimberley norm at 17 C in July and -8 C in January.

The ravines are well timbered with spruce, larch, lodgepole pine, alpine fire, white pine and thick underbrush. The upper elevations exhibit much less forest cover.

The property is drained on the west by Perry Creek and on the east by Moyie River. Perry Creek originates from a number of small high elevation lakes on the Grassy Mountain range as well as the Mt. Baldy -Biggatini range. The creek flows northeasterly through the Morgan claim group.

Moyie River originates from lakes on the east side of the Mt. Baldy - Biggatini range and tributaries to the south from the Moyie range. The river flows easterly bypassing the southern edge of the property (See Figure 2).

1.3 Claim Information

The Purcell property is comprised of 49 mineral claims of 414 units. The property is divided up into four blocks, in relation to individual ownership. Neigh-bouring claims are held by Gallant Gold Mines Ltd., Unique Resources, TransArtic Resources, Imperial Metals, Amstar Corp., and Leask Group (Goldpac) (See Figure 3).

1.31 The Morgan Claims

The Morgan claims of Perry Creek comprise of 5 mineral claims of 28 units in the North Block and 22 mineral claims of 144 units in the South Block. The Morgan claims, designated as either RACKI or LDM are all located within the Fort Steele Mining Division of B. C. (See Figure 4 - Claim Map). The claims are owned by L. Morgan of Cranbrook, B. C., F. Fairclough of Cranbrook, B. C. and N. Gass of Calgary, Alta. The property has been optioned by Chapleau Resources Ltd. for a 60% interest.

1.32 The Buck I Claims

The Buck I claims of Moyie River, comprising of 7 contiguous mineral claims of 90 units are all located within the Fort Steele Mining Division of B.C. (See Figure 5 - Claim Map). The claims are wholly owned by D. Melenka of Cranbrook, B.C. The property has been optioned by Chapleau Resources Ltd. for a 60% interest.

1.33 The Buck II Claims

The Buck II claims of Moyie River, comprising of 6 contiguous mineral claims of 62 units are all located within the Fort Steele Mining Division of B. C. (See Figure 5 - Claim Map). The claims are wholly owned by C. Kennedy of Cranbrook, B. C. The property has been optioned by Chapleau Resources Ltd. for a 60% interest.

1.34 The Bar Claims

The Bar claims of Moyie River, comprising of 9 contiguous mineral claims of 90 units are all located within the Fort Steele Mining Division of B. C. (See Figure 6 - Claim Map). The claims are wholly owned by Chapleau Resources Ltd.

1.4 History

The Perry Creek and Moyie River drainages were the scene of an intense gold rush near the turn of the century, having been the most prolific placer gold producers in the East Kootenay Region. Prospectors of the past explored by driving adits, sinking shafts and digging numerous hand trenches.

In Perry Creek, the Running Wolf mine (Figure 4) on French Creek has over 1000 feet of adits. The Homestake boasts a 560-foot tunnel and a 60-foot shaft. On Rome Creek, thirteen opencuts tested a two foot to 25-foot vein over 1500-feet in length. The Montezuma tunnel at the base of the Perry Creek Falls was driven in over 2000 feet to investigate the old channel.

Old records are scanty, but two bulk samples are on record: The Yellow Metal Group yielded .4 oz/ton Au from a one ton sample and a 3 ton sample from the Homestake gave .3 oz/ton Au. The Shakespeare group reported up to .75 oz/ton Au. The Excess, Rory, Red Mt., O'More, and Evil Genius claims all reported around .5 oz/ton. In 1973, a 1375 ton bulk sample from Quartz Hill ran .26 oz/ton gold, .2 oz/ton silver (Figure 4). Several of the veins carried gold and although no major deposit was discovered, several small shipments are reported.

In the Kiakho Creek area of the Moyie Range, numerous adits and shafts have been located adjacent to the syenite intrusion. Other small diggings of a lesser extent do occur along the diorite sills in various areas over the map area.

Immediatelly south of the property, several placer operations have worked the Moyie River to present day. Two such operations namely Kokanee Placer and Queenstake Resources are successfully producing gold in paying quantities.

1.5 Economic Potential - Geological Interpretation

The mineral deposits of Cranbrook area are many and varied. For purposes of description they have been classified into three main types:
A) replacement deposits in sedimentary rocks, not localized along fractures.
B) deposits associated with Moyie intrusions.
C) veins and replacement deposits localized along fractures.

The Sullivan and North Star deposits are representative of the first type. Deposits of the second type, associated with Moyie intrusions have produced smaller mineral occurrences on a reduced scale due to their erratic distribution. The third type included the more promising prospects in the area. They include the early attempts at gold mining, made at such workings as Anderson, Birdie Load, Rice, Homestake, Running Wolfe in Perry Creek, and Prospector's Dream in the Moyie.

1.6 Summary - Work Programm 1987

In 1987, from May 23 to November 22, field work, at a total cost of $105,000, conducted by Chapleau Resources Ltd., entailed the following:

A. Geological Survey
Detailed geological mapping was completed over the entire Morgan group of claims. The structural and lithological features confirmed previous mapping results of the area. The mapping also unveiled a number of interesting zones worthy of further study

B. Geochemical Survey
Soil, silt, bulk, and rock chip sampling was carried out over the recommended areas that highlighted mineralization and shear zones. A total of 3,256 samples taken over the entire Purcell camp were analyzed for Au, Pb, Cu, Zn, and As. Total soils collected amounted to 2,678 samples from 16 baselines, while silt samples totalled 172 from 7 drainages. Grab samples assayed totalled 390 specimens while 16 bulk samples were taken from 10 drainages.

C. Physical Work
A total of 51 trenches were excavated over anomalies found by the combined assay results of soil sampling and systematic rock chip sampling.

2.0 GEOLOGY

The following descriptions of the geology of the Purcell Range and the Perry Creek area are taken from G.S.C. Memoirs by Schofield, Rice and Hamilton.

2.1 Regional & Local Lithology

The Purcell Range is separated from the Selkirk range on the west and from the Rocky Mountain system on the east.

The rocks of the Purcell Range form the western part of the ancient group of sediments deposited in the Rocky Mountain geosyncline. These sediments, called the Purcell series, and of Pre-Cambrian Beltian age, consist of a great thickness of fine grained quartzites, argillaceous quartzites, argillites and limestones, all remarkable for their homogeneity.

In southeastern British Columbia, the Purcell Super group exceeds 10,000 m in thickness. In the vicinity of the Sullivan deposit at Kimberley the lowermost subdivision of the Purcell Supergroup, the Aldridge formation, is a 4,000m thick succession of fine-grained siliclastic rocks. Most of the Aldridge Formation was probably deposited by turbidity currents. East of Kimberley, in the western Rocky Mountains, the oldest rocks are greater than 2,000m thick, fining-upward platformal/deltaic sequence called the Fort Steele Formation. A transitional contact exists between the Fort Steele and the succeeding Aldridge Formation. The Fort Steele Formation is interpreted to be the facies equivalent of the lower part of the Aldridge Formation in the Kimberley area.

The Aldridge Formation is gradationally overlain by up to 1,800m of grey, green and maroon wacke of the tidal flat to deltaic Creston Formation. Conformably overlying the Creston Formation is 1,200m of dominantly platformal dolomite and terrigenous-dolomite admixtures of the Kitchener formation. The Kitchener is in turn overlain by 200 to 400m of green, slightly dolomitic and calcareous fine-grained sedimentary rocks of the Van Creek Formation and up to 500m of andesitic volcanic rocks of the Nicol Creek Formation.

In the Purcell Mountains, about 1,200m of grey to dark grey, dominantly platformal carbonates and fine-grained siliciclastic rocks of the Dutch Creek Formation rest with apparent conformity of the Lower Purcell sequence. The Dutch Creek Formation is overlain by 1,000m of grey, green and maroon wacke and buff orthoquartzite of the Mount Nelson Formation.

Middle Proterozoic gabbros of two ages intrude the Purcell Supergroup in southeastern British Columbia The oldest (1433 + 10 Ma) are sills, slightly discordant sheets and dykes of the Moyie Sills, which are most commonly developed in the lower part of the Aldridge Formation. Gabbro sills are most abundant in the Purcell Mountains, where they attain an aggregate thickness of up to 2,000m. The youngest event of gabbro intrusion is thought to be comagmatic with the volcanics of the Nicol Creek Formation, and is represented by abundant sills in the upper part of the Creston Formation and in the Kitchener and Van Creek Formations. Potassium-argon methods indicate an age of 1075 Ma for the Nicol Creek Formation.

The claim area studied is underlain by Precambrian sedimentary rocks of the Proterozoic age, either of the Kitchener, Creston or Aldridge formations.

In the Perry Creek area, the Creston and Kitchener Formations predominate, and are lenticularly Northeast trending, commonly in a fault contact and bounded to the North and South by the Aldridge Formation. The Aldridge formation outcrops predominantly within an area south and east of the Baldy and Cranbrook faults -on the Moyie River side. Precambrian diorite sills are distributed throughout the map area, in concentrated form along fault zones.

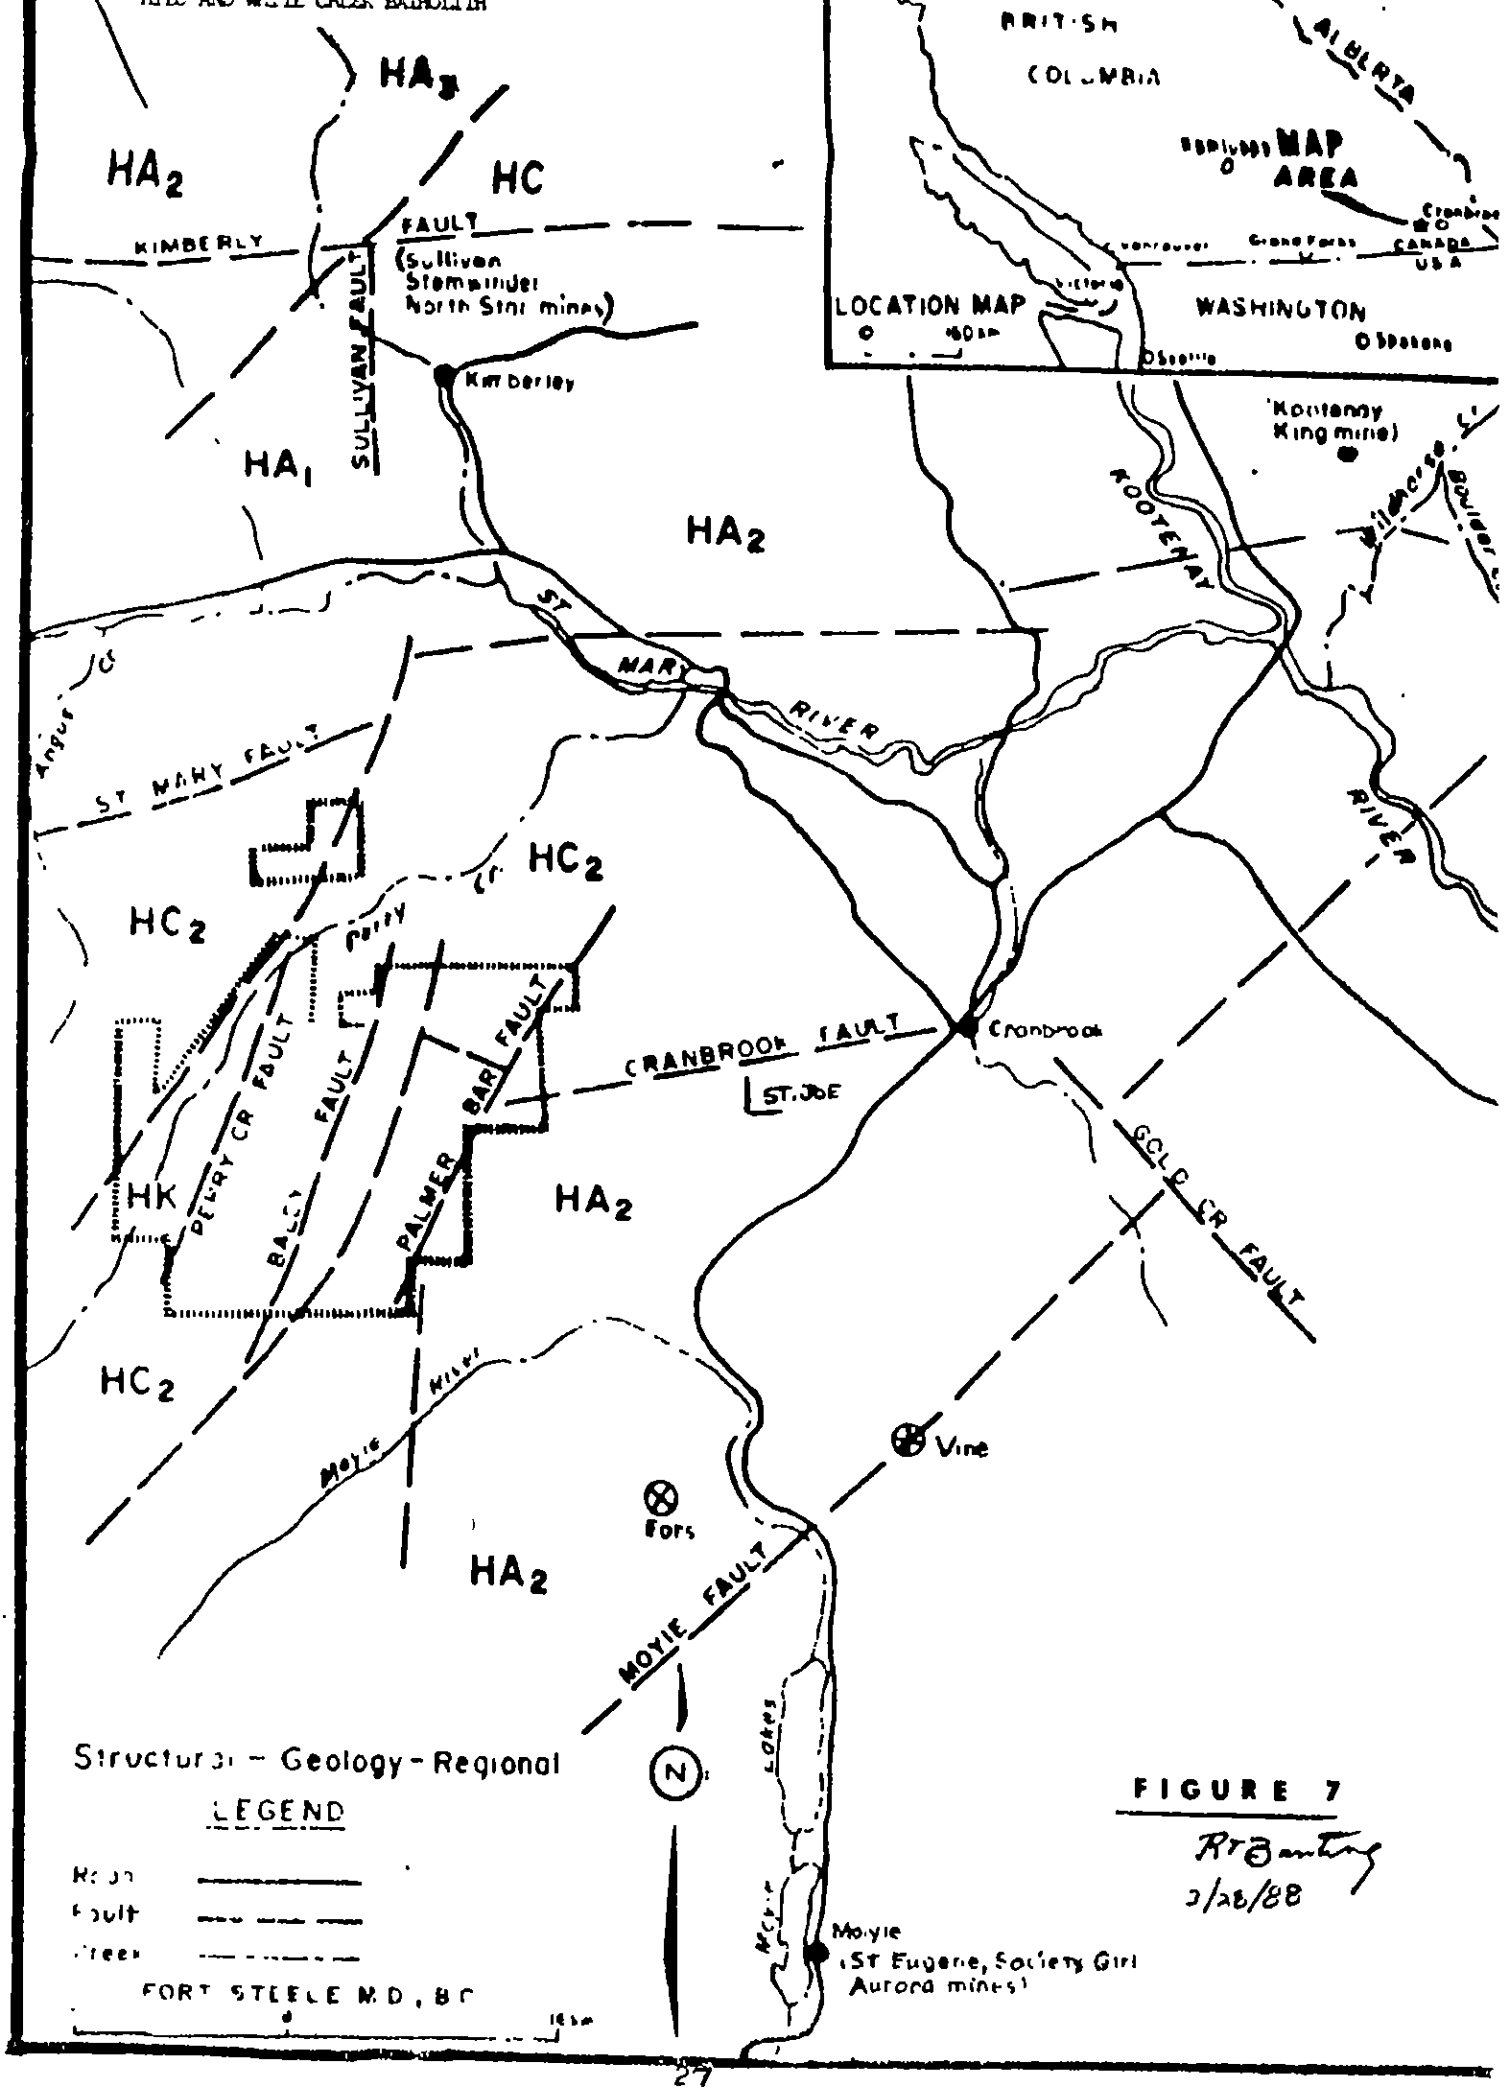

FIGURE 7

RT Bamford
2/28/88

2.2 Regional Mineralization - Sulphide Prospects

The Kimberley area is transected by the right lateral transverse St. Mary's fault. The Sullivan deposit occurs at the boundary between the Lower and Middle Aldridge within the St. Mary's block, with the North Star and Stemwinder deposits located just to the south.

The Sullivan orebody is interpreted as a hydrothermal synsedimentary sulphide lens which formed in a sub-basin on the marine floor during deposition of the Aldridge Formation. It is located directly over and adjacent to conduits through which mineralized fluids passed.

The evidence relating stratiform mineralization to syndepositional faulting is found in the coarse conglomerates which occur close to the lower and middle Aldridge contact. Conglomerate is found on the footwall at this horizon beneath the stratiform Sullivan deposit and below the Hilo mineral showing (north of the Hall Lake fault). The conglomerate underlies a thin stratiform pyrrhotite laminated zone. Pyrrhotite fragments in the conglomerate also occur in the Kootenay King deposit in Boulder Creek (See Figure 7).

Slightly east of the property claim block, on the St. Joe property, quartz veins mineralized with galena, chalcopyrite and arsenopyrite are found cutting the Middle Aldridge. Mineralized conglomerate is also reported to have originated from these workings.

In recent years, exploration of the area has been advanced by developments which include:
- the recognition of laminated markers (varves) and their use in subdivision of Aldridge stratigraphy.
- the recent discovery of the lead-zinc VINE deposit, located 40km. southeast of the Sullivan mine (the deposit crosscuts stratigraphy and appears to be of St. Eugene type).
- the discovery of lead-zinc float boulders at the Fors Grid prospect (40km. south of the Sullivan) leading to exploration of bedding controlled mineralization which might have occurred at a higher level than Sullivan time.
- the discovery of finely laminated pyrrhotite-pyrite beds in silty argillite that may be equivalents of the Sullivan deposit in diamond drilled holes east and southeast of the Sullivan deposit.

2.3 Local Mineralization - Gold Prospect

The following is part of the report submitted by G. Rodgers, Geologist, as mapped over the entire Morgan group of claims (Lithology and Structure in Appendix).

MINERALIZATION

Known mineralization is directly related to faulting and subsequent hydrothermal activity. As previously mentioned under 'Structure', the lensoidal diorite bodies control faulting somewhat by refracting the break around their margins. If the fault strikes through the diorite at a high angle, there is a high probability of void space being created and the void acts as a reservoir. This is due to the competency contrast between the diorite and the surrounding argillites and quartzites. Another potential reservoir for ore bearing fluids is at the locii of intersecting faults.

The majority of known showings and workings occur at similar elevations and along trend with the major longitudinal Perry Creek Fault and Richmond Lake Fault. It is possible that the graben created between these two faults may host undiscovered mineralization if the mineralizing event predates faulting.

Historically, the only showings of merit have been mined for their gold content. The gold has been found associated with quartz veins and shear zones as vein faults, stringers and lenses commonly enriched in iron (pyrite and its oxidation products) and less commonly enriched in lead, zinc and copper and their oxidation products. Chloritization and sericitization has affected the wall rock.

At least two phases of silica flooding have occured The first being milky white quartz which did not bring with it gold, but formed coarsely crystalline lenses, pods and at times huge irregular masses of quartz carrying iron visible at surface as pyrite and specular hematite. A second period of silica deposition occured leaving transparent quartz in interstitial voids and carrying with it gold and sometimes silver, zinc and copper.

The gold was channeled to zones of greater dilatency along strike of the faults where, since all major showings share a similiar elevation, the level of erosion puts these showings in the epithermal model just below the silica capping. Temperatures were probably cool (100 C).

The topographic recession of vein surfaces hints that supergene enrichment has taken place but to what depth is as yet uncertain.

3.0 GEOCHEMISTRY

3.1 Introduction

This report addresses the results of the soil and stream sediment geochemical surveys which were undertaken during the 1987 field season on the Morgan, Buck and Bar Properties, Cranbrook, British Columbia by Chaplean Resources. Exploration targets on the properties, which also occur in similar host lithologies and geologic settings nearby, include sediment-hosted massive-sulphide mineralization similar to that at the Sullivan Mine and precious-metal (± base-metal) quartz veins, perhaps similar to those on the east side of Moyie Lake (the St. Eugene Mine). Possibilities also exist for bulk-tonnage low-grade replacement-type Au deposits in calcareous stratigraphy of the Purcell Supergroup.

Discussions of the results of these surveys are included separately (see references) and are based largely on statistical analyses of the geochemical determinations, and based on maps of the geochemical concentrations. This report summarizes the results and conclusions of these reports and looks at these results in an overall exploration context. Recommendations for further geochemical work on the property during the 1988 field season are also presented.

3.2 Conclusions - Stream Sediments

Stream sediment data from the Morgan, Buck and Bar Properties successfully identifies several stream sediment anomalies. Four of these occur along Wuho Creek and could be related to massive sulphide mineralization. A fifth anomaly occurs near the head of Noke Creek. (Fig.5 p8;s.s.p148,151)

'Anomalous' concentrations of Cu, Pb, Zn, Ag, As ± Au downstream from the anomalous sources indicate that Cu, Pb, Ag, As and Au appear to have shorter dispersion trains than Zn.

The design of the stream sediment survey is clearly inadequate to accurately define drainages 'anomalous' in Au. The sampling density of the survey, the size of the sample collected and analyzed, the sample preparation technique and the analytical procedure also prevent recognition of known metal occurrences. Furthermore, geochemical contrast for most elements is not adequate to define 'anomalies' with confidence.

3.3 Conclusions - Soil Grids

Several 'anomalous' zones are observed on the many soil grids located on these properties. Those possibly related to massive sulphide mineralization occur on Soil Grids BSW-1/BSW-3, BSW-2 of the Buck Property and on the Gossan Hill and Quartz Pit/Horseshoe Soil Grids of the Bar Property. These are generally comprised of a distinct Pb 'anomaly' with 'anomalous' concentrations of Cu, Zn and As nearby. The patterns defined by these 'anomalies' suggest that, like the stream sediments, differential element mobility has acted to create different 'anomaly' geometries and intensities.
(Buck Fig.5 p8;p90) (Bar Fig.6 p9;p114)

Other geochemical 'anomalies' occuring on the properties consist of linear trends defined by one or more element. These occur on the Morgan # 4 Gird, where 'anomalous' As occurs at the intersection of 'anomalous' trends of Cu and Pb, and on the Noke Grid, where 'anomalous' Cu, Pb and As define two E-W oriented trends. These 'anomalies' may be related to sulphide bearing structures underlying the soil grids. These structures may also contain Au. (Morg Fig.10b p29;p49) (Buck Fig.5 p8;p90)

While the general soil survey design appears to be barely adequate to allow definition of massive sulphide targets, the geochemical contrast produced by the sample collection, reduction and analysis procedures is clearly not as high as that generally observed in the stream sediments. This soil survey design seems totally inadequate to locate known sources of Au mineralization, even when samples are collected immediately adjacent to and above prospects. For both massive sulphide and Au vein targets, higher sample densities would allow for greater confidence in anomaly detection.

3.4 Synopsis

In general, element concentrations have large levels of variation across short distances. This is probably due to inadequate sampling technique and probably resulted in the misinterpretation of 'anomalous' signatures and the non-detection of possibly several significant 'anomalous' zones. Sample sizes do not appear to be large enough to allow interpretation of Au concentration distributions. Also, the sampling, perparation and analytical procedures do not produce adequate contrast to allow easy and confident interpretation.

Patterns of concentrations of elements from both stream sediments and soils do show evidence for differential mobility. Specifically, Zn concentrations appear to be dispersed substantial distances from Pb 'anomalous' zones considered to be their source. Concentrations in stream sediments are generally higher than those in soils defining the possible source for the stream sediment 'anomaly'. This may be due to dilution of the soil samples by fine grained glacial till which does not contain significant concentrations of the elements.

Based on the observed patterns of element concentrations on the soil grids and in the stream sediments, there is little evidence to suggest the presence of disseminated, micron-sized Au replacement mineralisation. The low reproducibility of the Au determinations suggests that a large nugget effect affects the results. This nugget effect is probably due to coarse grained native Au particles occurring in the samples, and could not be produced by micron-sized Au grains. The large As 'anomaly' located on the Morgan # 4 Grid is the only evidence which may suggest the presence of fine-grained Au replacement mineralisation, because the equi-dimensional form of this anomaly does not appear to be controlled dominantly by structures.

3.5 Recommendations for 1988

Based on the above observations and conclusions, the following actions are recommended :

- an orient[illegible]rvey of the stream sediment collection method, using one of the obs[illegible]ed anomalies on Wuho Creek as a test case; from this an optimal sa[illegible]pling design and set of analytical procedures can be determined which will give confident detection of anomalies related to both massive-sulphide and Au-quartz vein mineralisation;

- a detailed stream sediment survey of all streams on the property (based on the above described orientation survey) at one sample every 250 m along the stream and above all forks; this should include a multi-element (+ Hg) ICP analysis of the silt fraction plus a non-magnetic and magnetic heavy liquid separation of up to 5 kg of fine grained stream sediment; analysis of Au should be by fire assay pre-concentration and atomic absorption; a barite specific determination should be included; this survey should take place immediately after spring run-off to avoid hydraulic re-distribution of heavy minerals;

- anomalous zones discovered by the 1987 stream sediment survey should be confirmed with this detailed stream sediment survey; bank sampling of the suspected anomalous zones should be done in conjunction with this survey to further constrain the location of the sources for these stream sediment 'anomalies';

- all confirmed stream sediment anomalies should be intensively prospected and covered with an extensive soil grid over the most likely locations; sample spacing should not be larger than 25 m; analysis of the -80 mesh fraction should include an ICP multi-element (+ Hg) determination plus Au by fire assay pre-concentration and atomic absorption finish; a barite specific analysis should also be included if found to be of value in the stream sediment and soil orientation (see below) surveys;

- an orientation survey of the soil method for both massive sulphide and Au vein targets, using several of the known showings as test cases; from this an optimal sampling design and set of analytical procedures can be determined which will give confident detection of anomal[illegible] related to massive-sulphide and Au-quartz vein mineralization;

- before the commencement of any soil survey, an assessment of the glacial overburden and its effect on the detection of geochemical anomalies must be undertaken; this should include a study of the soil and overburden stratigraphy and provenence;

- future soil grids should be located in known prospect areas where mineralisation has been observed or as indicated by regional stream

sediment and bank sample results; these should cover large areas to ensure that ore-related geochemical signatures are not missed due to glacial dispersion; small numbers of samples in soil grids are not recommended because little information regarding the relative concentration can be obtained;

- future soil grids should have nodes at 25 m or less to allow enough sample to represent possible'anomalous' zones; analysis of the appropriate sample size fraction should include an ICP multi-element (+ Hg) determination plus Au by fire assay pre-concentration and atomic absorption finish; a barite specific analysis should also be included if found to be of value in defining stream sediment and soil 'anomalies' related to massive sulphide mineralization;

- geophysical methods should be employed over known Au vein showings and in several of the massive sulphide target areas; if useful, these should be integrated into the exploration procedure and used to the best advantage.

4.0 CONCLUSION

It is the expressed opinion of the writer that the structural and lithological geology of the area contrasted with the findings of the 1987 exploration program indicate that the possibility exists for a potential mineral orebody on the Chapleau Property.

With respect to the Morgan property, Mr. Rodgers has presented two theories supporting potential gold deposits in the Perry Creek area.

One theory offers the prospect of gold discovery in quartz veins similar to those mined at the turn of the century. It is hypothesized "that detrital gold was formed at a certain horizon in the Aldridge, by the weathering of a proximal archean source. Subsequent faulting and hydrothermal activity scavanged this gold near to fault zones and redeposited it as lode gold in vein faults. Most showings of merit in the area occur at elevations between 5000 and 6000 feet. All showings consist of vein faults displaying silica deposition along with iron oxides and gold of a nature typical to epithermal veins".
The recently discovered stock work of veins found in the BUCK and BAR properties, typically similar to the old Perry and Moyie workings show promise, with visible gold and assays up to .6 oz/ton.

"If the hypothesis of detrital gold at a certain horizon can be substantiated, then a target area for a large tonnage gold deposit then exists at depth in the valley bottom between the Perry Creek and Richmond Lake faults. Diamond drill holes in the middle of the Kitchener argillites would test the validity of this theory." The common features in the description of a replacement type orebody can be traced to the subject property, as evidenced by:
a) a driving mechanism such as a tertiary felsic magma body in the area of the headwaters of France Creek; where syenite float was discovered on both sides of the ridge.
b) steeply dipping shear zones such as the Cranbrook fault, whereby the magnetic anomalies in preferential alignment with the intrusions of Kiakho Lake and Grassy Mountain suggest a continuation of the fault to the west.

c) associative elements such as arsenic found as an anomalous zone on the Morgan #4 Grid (See Geochemical Synopsis - P.31).
d) high fineness gold particles as found in the stream silt samples and placer operations in the Moyie and Perry Creeks.

In contrast to the potential for a gold deposit, there is also a strong indication that the possiblity exists for a sulphide deposit on the BAR and BUCK group of claims. This supposition is evidenced by the structural features of the Palmer Bar region, the favourable stratigraphy of the underlying formations and the anomolous geochemical values obtained from the area drainages (See Geochemical - Conclusion - P.30).

5.0 RECOMMENDATIONS

The following recommendations are offered as part of the Phase II Work Program for 1988.

Zone 1, 2, 3

- Detailed sediment survey of all streams on the western ridge betwen France and Strong Creeks and on the eastern ridge between Palmer Bar and Noke Creeks.
- Reconnaissance geological mapping and prospecting over the BUCK and BAR claims to confirm stream sediment anomalies.
- Geophysical surveys (EM & IP) on the Buck and Bar to map Au vein systems such as the ELCR, Horseshoe and Gossan Hill as well as several of the massive sulphide target areas.
- Selection of drill target areas to;
  a) test known gold bearing veins to depth
  b) substantiate the existence of a felsic intrusion
  c) determine the source for the stream sediment and soil anomalies related to massive sulphide mineralization.

Zone 4, 5, 6

Detailed (10m) soil sample program integrated with prospecting in order to delimit the anomalies already determined, thereby more accurately locating the diamond drill hole targets in Shorty Creek, Liverpool Creek, and Wuhun Creek areas.

Phase III

Contingent upon the results of Phase II, Phase III will be an extension of the 1988 drill program. The estimated cost of this phase is $400,000.00.

STATEMENT OF QUALIFICATION

I, ROBERT T. BANTING, certify that:

1. I am a Consulting Mining Engineer, of R.T.Banting Engineering Ltd., with offices at 1470 Theatre Road, Cranbrook,B.C.

2. I am a graduate of Michigan Technological University with a degree in Mining Engineering (B.Sc.)

3. I have practised my profession of engineering in British Columbia, Manitoba, Ontario and Quebec for a total of 14 years. As a consultant, I have been engaged in exploration and engineering activities for four years.

4. I am a member in good standing of the Association of Professional Engineers of British Columbia.

June 10, 1988

Geologist – G. Rodgers

I, GLEN M. RODGERS, certify that:

1. I am a graduate Geological Engineer from the University of Manitoba (1977).

2. I have practised the profession of Geologist for the last eleven years in B.C., the Yukon and Alaska.

3. I have gained experience with; epithermal silver and gold vein deposits, gold placer deposits, stratiform lead/zinc/silver deposits, uranium deposits, evaporite and other industrial mineral deposits. I have gained experience in all facets of mineral exploration techniques.

4. I am a fellow in good standing of the Geological Association of Canada, and am eligible for membership with the Association of Professional Engineers of British Columbia.

March 14, 1988

R.T.Banting PEng.,
c/o Chapleau Resources Ltd.,
2100 - 4th St. N., V1C 4X9

Dear Mr. Banting,

This letter is to authorize you to use all or any part of the geological reports and maps that I have submitted on the Morgan claims, Perry Creek for the years 1987 and 1988.

- Yours Truly,

(G.M. Rodgers, geologist)

Certificate of Qualifications

I, Clifford R. Stanley, of 3503 W. 20th Ave., Vancouver, British Columbia, hereby certify that :

1. I am a graduate of Dartmouth College (1980) and the University of British Columbia (1984) and hold an A.B. in Earth Science and an M.Sc. in Geological Science.
2. I have been employed in the mineral exploration field in permanant and consulting roles since 1980 as an exploration geochemist and economic geologist.
3. I am currently a principle of CyberQuest Exploration Systems, Ltd. and in their employ.
4. The opinions, conclusions and recommendations contained herein are based solely on an examination of geochemical data provided to me by Chapleau Resources, Ltd. of Cranbrook, British Columbia.
5. I own no direct, indirect or contingent interests in the subject property or shares or securities in Chapleau Resources, Ltd.
6. This report and its contents may be used by Chapleau Resources, Ltd. for all corporate purposes, including public financing.

Clifford R. Stanley

Dated in Vancouver, B.C. this 18th day of March, 1988.

I. Morgan Geology - G. Rodgers

LITHOLOGY

The following formations are found in the claim area and are described here in order of oldest to youngest.

ALDRIDGE FORMATION

The Aldridge Formation (Ha) is commonly divided into 3 parts: upper, middle and lower. The Sullivan Mine is found at the lower-middle Aldridge contact. As the divisions between the Aldridge sections are difficult to distinguish and vary both across and along strike, the Aldridge formation as a whole is described here.

The Aldridge formation is the lowest member of the Purcell Group and as close as can be determined, it is proterozoic in age. Total formational thickness probably exceeds 15,000 feet (4570m). The Aldridge consists of grey-brown-rusty weathering, very fine grained, thin bedded quarzite, sericitic siltstone and argillaceous quartzite. The quartzites are commonly thin bedded, purple-grey-white-black. Pure argillite or slate forms a minor constituent. Primary depositional features such as scour and fill or cross-bedding are common.

The quartzite beds locally are thick bedded-massive The interbedded argillite is thinly laminated and occasionally finely laminated. Other primary depositional features such as dessication cracks, ripple marks, etc. are not common.

The Aldridge Formation occurs north of the St. Mary Fault and west of the Racki 10 claim. It is in fault contact with the Creston Formation to the south. Near this fault contact, the Aldridge Formation is locally sheared, faulted and folded.

CRESTON FORMATION

A gradational contact over 150m separates the under lying Aldridge Formation from the Creston Formation The Creston Formation is primarily composed of greyish argillaceous quartzites. Minor purer quartzites and argillites form interbeds of up to 0.3 m thick. The formation as a whole resembles the Aldridge, but the purer quartzites are more abundant and are light grey on fresh fracture. The Creston Formation varies in total thickness between 4,000 ft. (1220 m) and 6500 ft. (1980 m). It has been divided into 3 sections:

- the Lower Creston (HC1) consists of black-grey argillites with interlaminated, lighter-coloured argillaceous quartzite. These laminae, pinch, and swell along strike. Other minor constituents are: very fine grained, sericitized, siliceous siltstones (which are dark coloured and weather rusty brown) and green argillaceous quartzites (found near the top of the Lower Creston Formation). Features suggesting shallow water deposition such as mud cracks, ripple marks, cross beds, and slumping are common in the Lower Creston.
- the Middle Creston Formation (HC2) is not as argillaceous as the Lower Creston Formation and constists primarily of grey-green-purple argillaceous quartzite. These predominantly purple quartzites form thick beds (0.3 to 3 m) and resemble limestone from a distance.
- the Upper Creston (HC3) consists of grey-green argillaceous quartzite with thick interbeds of purple argillite. Near the top of this unit, white-grey-purple argillaceous quartzites are most common with fine laminae of a dark purple quartzite being it's most distinctive feature. This banding effect is due to seasonal changes in depositional climate. Shallow water depositional features are common.

KITCHENER FORMATION

The Kitchener Formation (Hk) lies unconformably upon the underlying Creston Formation. This formation consists of calcareous and argillaceous quartzites, quartzites and limestones. It weathers to a yellow-brown-grey. Leaching of calcareous minerals often leaves linear depressions on weathered surfaces. The main constituents are; very fine grained rusty-red-brown weathering quartzites and siltstones; fine grained buff dolomite; black limestone; impure limestones and argillites. The argillites are characteristically dark-light green in the lower part and black-grey-white in the upper part. The carbonate content, thin bedding and preferential weathering of carbonate are all features distinguishing this formation from others. Total formational thickness is thought to exceed 4,500 ft (1370 m).

Above the Kitchener Formation conformably sits the Siyeh Formation the contact of which is marked by the presence of igneous breccia and tuff. The Siyeh Formation is not found in the map area.

MOYIE SILLS

The Moyie Sills are also known as the Purcell Sills Purcell Intrusives, Moyie Intrusives and St. Mary's Sills. These are sill like intrusions that range in thickness from 10 metres to 300 metres. The sills were injected when the strata was still horizontal as they have subsequently undergone the same tectonism as the surrounding rock. They are most commonly found in the Aldridge Formation but also penetrate through to other formations from horizon to horizon and can pinch out along strike. They are termed diorites, but range in composition from gabbro to granite. Commonly a contact metamorphic effect with the country rock is evidenced by albite and biotite addition. These sills represent intrusions from a single intercrustal source of acid magma. The age of these intrusive rocks has not been accurately determined, but definitely post dates that of the Kitchener Formation and are possibly of late Proterozoic age.

The diorite sills are found on the property as lenticular bodies up to 400 ft. (122 m) thick. They follow the general strike of the bedding (N 30' E) and are found in Perry Creek mostly at lower elevations.

The diorite sills are found on the property as lenticular bodies up to 1,000 ft. (300 m) thick. Two smaller sills are found on the Racki 10 claim and a very large diorite sill is found to touch on the south-east corner of the Racki 4 claim.

CRANBROOK FORMATION

The Cranbrook Formation forms a very small percentage of the total study area. It consists of light brown-tan-grey siltsones, argillites and argillaceous quartzites. It is known to be lower Cambrian in age and contacts unconformably with the Kitchener Formation in the south-east corner of the map area.

STRUCTURE

Broad scale, regional folding is not apparent in the map area. Smaller scale deformations are occasionally found, but can usually be attributed to drag folding due to nearby fault action or to post emplacement movement of nearby diorite bodies. The Moyie Intrusives, because of their competency contrast with the surrounding argillites have served to locally control fault direction. Low angle faults tend to refract around the perimeters of the lenticular diorite bodies. Higher angle faults tend to break right through the diorite lenses creating offsets. When proximal to major faulting, the sills often exhibit a reoriented foliation parallel with that major deformational event. If the deformation has been intense, then the foliation permeates the entire sill. If the deformation has not been so strong, then foliation occurs only near to and parallel with the contacts.

Major longitudinal faulting has been confirmed in map area. Faults known as the Perry Creek Faults, Richmond Lake Fault and Baldy Fault strike north-east across the map area. These faults predate the many less intense transverse faults which break orthogonal to the major faulting and generally strike north-east. These transverse faults were probably responsible for localizing the main drainages that empty into Perry Creek.

Divergent bedding in the bottom of Perry Creek near Shorty Creek previously mapped as the "Perry Creek Anticline" does not (in this authors' opinion) exist. A package of rock thought to be Upper Creston in stratigraphy is exposed here at it's contact with the overlying Kitchener Formation. It is this obscure unconformable contact that gives the impression of anticunal folding.

The Perry Creek Fault has been mapped on the basis of lithological and bedding plane changes, while foliation remains constant on either side of the fault. For most of its length in the claim area, the Perry Creek Fault separates Middle Creston to the east from Kitchener to the west.

On the west side of the Perry Creek Valley, the Richmond Lake Fault divides Middle Creston to the west from Kitchener on the east.

The St. Mary's Fault separates Upper Aldridge sediments to the north from Middle Creston to the south It also divides a diorite body on the Quartz Hill claim at Upper Sawmill Creek.

In the vicinity of Paris Creek, these two major faults converge. Between the two, a graben exists with unknown total displacement. It is suspected that the Perry Creek Fault exceeds that of the Richmond Lake Fault.

A PRELIMINARY REPORT ON THE 1987 SOIL GEOCHEMISTRY OF THE MORGAN PROPERTY, CRANBROOK, BRITISH COLUMBIA

John Harrop Clifford R. Stanley

CyberQuest Exploration Systems, Ltd.
Suite 210 - 830 W. Pender St.
Vancouver, B.C. V6C 1J8

March 18, 1988

1 Introduction

This report addresses the results of the soil geochemical surveys which were undertaken during the 1987 field season on the Morgan Property, Cranbrook, British Columbia by Chaplean Resources. Exploration targets on the property, which also occur in similar host lithologies and geologic settings nearby, include sediment-hosted massive-sulphide mineralization similar to that at the Sullivan Mine and precious-metal (± base-metal) quartz veins, perhaps similar to those on the east side of Moyie Lake (the St. Eugene Mine). Possibilities also exist for bulk-tonnage low-grade replacement-type Au deposits in calcareous stratigraphy of the Purcell Supergroup. A discussion of the results of these surveys is included based largely on a statistical analysis of the geochemical determinations, and based on maps of the geochemical concentrations. Recommendations for further geochemical work on the property are also presented.

Sampling was carried out by Chapleau Resources' employees during August through September 1987 and all geochemical element determinations were made by Rossbacher Laboratory, Ltd. Samples consisted of 0.5 kg of fine grained stream sediment material collected from the active bed of the streams. These were air dried and seived to -80 mesh. A 0.5 gram sub-sample was digested with a 3:1 nitric:perchloric acid attack and analysed using atomic absorption spectrometry. Elements determined include Cu, Ag, Pb and As for all four soil grids and Zn analyses for some samples on the Morgan Grid # 4. Gold was determined by a similar method, except that 10 grams of -80 mesh material was subjected to an aqua regia digestion followed by pre-concentration in MIBK. No standards were included in the analytical batches so data quality could not be determined; however, several sample sites have duplicate samples allowing a rough assessment of sample site reproducibility.

Four soil grids (Morgan-1 through Morgan-4) were sampled and maps presenting the sample locations and geochemical concentrations for these samples are presented in Appendix A. The grids are, for the most part, oriented N-S with 50 m between lines and 50 m between sample sites (with some exceptions in areas of interest, where the sample spacing was reduced to 25 m between lines and 25 m between samples). The grids are irregular because numerous grid nodes could not be sampled.

2 Statistical Analysis

2.1 Threshold Selection

A histogram and probability plot analysis (Sinclair 1974, 1976; Stanley 1987) of the geochemical concentrations was made on all of the data from the four soil grids. Output of these statistical results are presented in Appendix B.

Results indicate that all elements have subdued abundances and exhibit positively skewed distributions. Low element abundances are common in Belt-Purcell soils, even over sulphide mineralization, because of the overall low absorptive capacity of the soils (low

clay and Fe-oxy-hydroxide mineral content; Stanley 1984). This allows the easy leaching of the soluble base metals from the soils, despite high element concentrations in the source-bearing subjacent bedrock. The positive skewness of the element distributions probably results from a large number of 'background' concentrations and a small number of 'highly anomalous' concentrations which may possibly be related to economic mineralisation.

2.1.1 Copper

The Cu distribution appears to have a bimodal, log-normal form. One mode consisting of a large group of samples, exhibiting what are interpreted to be 'background' Cu concentrations and a mean of 7 ppm. Assymetric ±1 standard deviation values about this mean are 13 and 4 ppm, respectively. A second group of samples of higher abundance can be distingushed from this 'background' group. These concentrations are interpreted to be 'anomalous' and range up to 124 ppm Cu. This second group of 'anomalous' samples may be related to lithologies containing elevated Cu concentrations or to Cu-sulphide-bearing strata. A threshold which discriminates the 'background' and 'anomalous' sample groups occurs at approximately 35 ppm.

2.1.2 Silver

Silver concentrations are positively skewed, of generally low abundance and have a maximum value of 1.2 ppm. The low number of reported concentration values does not allow rigorous statistical evaluation of the Ag data. The overall extremely low Ag abundances typical of B-horizon soil samples collected over Belt-Purcell strata (Stanley 1984) and observed on the Morgan Property cannot be considered to be indicative of the absence of economic mineralisation. As a result, concentrations in excess of (an abritrarily chosen) 3× the detection limit of 0.2 ppm are considered to be 'anomalous' because they have the highest probaility of resulting from nearby Ag-bearing sulphides which have undergone extreme weathering and depletion of the Ag.

2.1.3 Lead

Lead concentrations also exhibit a positive skew and have an overall low abundance (with a maximum concentration of 258). Lead appears to be log-normally distributed with minor negative deviation in lower concentrations (interpreted to be due to truncation of the distribution by the detection limit). The unimodal distribution does not suggest the existance of a distinguishable 'anomalous' group of samples; consequently, a threshold has been chosen at the 'mean plus 2 standard deviations' (28 ppm) to define the 'anomalous' samples.

2.1.4 Gold

Gold exhibits an obvious bimodal distribution consisting of samples with 'background' concentrations of up to 5 ppb and samples with 'anomalous' concentrations above 5 ppb.

While probably distributed poisson, this distribution can be approximated by a mixture of two log-normal distributions. Since gold probably exists largely in its native form in these soils, the 'background' sample group can be considered to be those samples where the analysed sub-sample contained no gold nuggets (and thus a concentration of 5 ppb). The 'anomalous' group of samples can be considered to consist of those samples where the analyzed sub-sample contained at least one grain of gold. Unfortunately, any 0.5 kg sample may contain numerous gold nuggets while a 10 gram sub-sample from it **may contain none**. As a result, given the small amount of sample collected and the small amount of material which was actually analyzed, samples from the 'background' group may contain significant concentrations of Au contained in nuggets not included in the 10 gram analyzed sub-sample. Nonetheless, a threshold of 10 ppb distinguishes the 'background' from the 'anomalous' samples.

2.1.5 Arsenic

Arsenic exhibits a trimodal log-normal distribution and relatively high overall concentrations. The lowest mode consists of detection limit values of 2 ppm and is probably a result of data truncation by the detection limit and the recoding of below detection limit concentrations to the detection limit value. The middle mode has a mean of 10 ppm (± 1 standard deviation values of 16 and 6 ppm, respectively), is probably more representative of the 'background' As concentration. The highest mode, with a mean of 45 ppm (assymetric $\pm$ 1 standard deviation values of 72 and 28 ppm, respectively) is probably 'anomalous' and may be related to sulphide-bearing strata. A threshold of 22 ppm separates the 'anomalous' and 'background' sample groups.

3 Interpretation

Interpretive symbolic maps of only those elements which showed what are considered to be significant patterns are presented in Appendix C. Circles have radii which are proportional to the sample concentrations. Heavy circles represent those samples which recorded a concentration in excess of 2× the largest circle size indicated. These plots are discussed in five sections related to each of the five soil grid areas (the Morgan # 3 grid has been divided into East and West sections relflecting the different base line orientation).

3.1 Morgan Grid # 1 (Locations p.29)

Gold is the only element discussed on Morgan Grid # 1. Incoherent patterns of concentrations are observed for all other elements. Gold is no exception. Trends of relatively high Au concentrations can neither be considered coherent nor significant. Two of the three sets of duplicate samples report the lowest **and** some of the highest concentrations observed on the soil grid. With such little consistency on a single site basis, no confidence can be

placed in any interpretation. However, one item which can be concluded is that a significant 'nugget' effect exists which has not been eliminated or reduced through deliberate sampling and analysis procedures.

3.2 Morgan Grid # 2

On Morgan Grid # 2, relatively high concentrations of Cu appear to define a NE-SW trend at the north end of the grid. This trend appears to be situated on top of and roughly parallel to an inferred photo-linear observed on air-photos of this area. This trend could represent a major fracture system across the soil grid which contains Cu-sulphide minerals. Alternatively,this trend directly overlies Perry Creek and could represent the different source material sampled (stream alluvium vs. colluvial/residual soil developed on glacial till) at these locations. Whether the Cu geochemical trend is due to an underlying Cu-bearing vein filling fracture, to hydromorphic concentration of Cu along a fracture system by fault gouge clays and Fe-oxy-hydroxides, or to a different source material is not known. Several relatively high cxoncentrations of Au in samples along this trend may suggest the former and later hypotheses as more reasonable conjectures.

3.3 Morgan Grid # 3 (East)

The eastern portion of the Morgan # 3 soil grid contains several important trends in Cu, Au and As. Relatively high Cu concentrations define three possible trends : one NE-SW trend in the NW corner of the grid, a parallel trend roughly bisecting the soil grid, and a NW-SE trend bisecting the NE quadrant of the soil grid. Obvious conclusions drawn from these observations are that they represent fracture zones related to possible Cu-bearing vein mineralization. Unfortunately, the hydromorphic concentration hypothesis described above cannot be ruled out.

High concentrations of Au appear to define a trend parallel to the NE-SW Cu trend which bisects the soil grid. Unfortunately, these high values are widely separated and several samples with 5 ppb Au concentrations lie in between, lending little significance to this interpretation.

Relatively high As concentrations appear to define two areas of interest in the NE and center portions of the grid, but on closer inspection, the boundaries of these areas are sharp and oriented exactly N-S. **This suggests that there is a systematic sampling error.** Patterns of this type suggest that at least two of the samplers (each sampling adjacent lines) had sampling techniques which produced systematically different 'background' As concentrations. The centrally located region of high As concentrations does appear to have a NE-SW elongation direction which does parallel one of the observed Cu trends.

No geochemical 'anomaly' can be interpreted over the Ravine Fault lying along Perry Creek.

3.4 Morgan Grid # 3 (West)

Geochemical concentrations on the western portion of the Morgan # 3 soil grid also show interesting patterns. Relatively high concentrations of Cu occur in the NW corner of the grid, and an area of elevated Pb 'background' concentrations occur in the SE quadrant. The Cu 'anomaly' may be related to a N-S trending inferred fault projected beneath the 'anomaly'. The Pb pattern is more enigmatic, roughly straddling Liverpool Creek. The highly 'anomalous' Pb concentration in the SE corner of the grid occurs immediately adjacent to Liverpool Creek and may represent hydromorphic or detrital reconcentration of lead at that site by stream waters.

Gold concentrations define two 'anomalous' trends, both of which may not be significant. A set of 5 samples roughly parallel to the N edge of the grid, and a perpendicularly oriented set of 3 samples in the SE corner of the grid define two trends. The causes of these trends are not hypothesized. The high Au concentrations occurring in the SW corner of the grid may, like lead represent detrital reconcentration of Au by Liverpool Creek.

Arsenic cencentration are 'anomalous' in the north-central protion of the grid in a NW-SE orientation; however, no explanation for this pattern can be offered.

3.5 Morgan Grid # 4

Geochemical patterns on the Morgan # 4 soil grid show the most coherent signature of all the soil grids sampled on the Morgan Property. The Cu and Pb concentrations define a NW-SE 'anomalous' trend which roughly bisects the soil grid and which is most developed on the wetern half of the soil grid. This trend is parallel and slightly north of the Spring # 1 Fault and appears to be related to it. The offset may represent glacial dispersion or a slight inaccuracy in the placement of the fault on the map.

Lead also defines a trend on the western half of the grid which is perpendicular to and which intersects this Cu and Pb trend. It extends to the northern edge of the grid and is roughly parallel to the mapped location of the Perry Creek anticlinal axis.

An As 'anomaly' centered over the intersection of these two trends in the western portion of the grid is the most distinct 'anomaly' on the property. These 'highly anomalous' As concentrations may be caused by hydrothermal mineralization centered at the intersection of these two, possibly fracture related, geochemical trends.

Gold concentrations on this soil grid are mostly at the detection limit and do not form any discernable trend.

4 Conclusions and Recommendations

Based on the results of the 1987 soil surveys on the Morgan Property, several conclusions may be drawn :

- the method of collection of the soil samples was not consistently identical across the grids;

- the sample size, preparation and analytical method for Au is inadequate to detect, with confidence, the presence of Au in the soils;
- the preparation and analytical method for the base metals does not produce adequate contrast to confidently define samples as 'anomalous';
- several distinct geochemical anomalies occur on the soil grids in the form of trends which parallel known structures (Cu and Au(?) on Grid # 2; Cu and Au(?) on Grid # 3 (East); Cu and Pb on Grid # 4);
- an 'anomalous' zone of As occurs on Grid # 4 at the intersection of the two Pb trends; it may be related to possible intense fracturing which could occur at the intersection of two fault structures;
- given the sample density of the grids (50 m) and the observed width of the quartz veins which have been mined historically (generally less than 3 m), only a small probability (¡ 10 %) exists of sampling material derived directly from the vein material;
- no information about the effect of the glacial cover can be discerned from the data; this till could be exotic and totally unrelated to the lithologies and possible mineralization which it covers.

Based on the above conclusions, the following actions are recommended :

- an orientation survey of the soil method, using one of the known showings as a test case; from this an optimal sampling design and set of analytical procedures can be determined which will give confident detection of anomalies related to massive-sulphide, Au replacement and Au-quartz vein mineralisation;
- before the commencement of any soil survey, an assessment of the glacial overburden and its effect on the detection of geochemical anomalies **must** be undertaken; this should include a study of the soil and overburden stratigraphy **and** provenence;
- future soil grids should be located in known prospect areas where mineralisation **has been observed** or as indicated by regional stream sediment results; these should cover large areas to ensure that ore-related geochemical signatures are not missed due to glacial dispersion; small numbers of samples in soil grids are not recommended because little information regarding the relative concentration can be obtained;

- future soil grids should have nodes at 25 m or less if indicated by an orientation survey; analysis of the appropriate fraction should include an ICP multi-element (+ Hg) determination plus Au by fire assay pre-concentration and atomic absorption finish; a barite specific analysis should also be included if found to be of value in the stream sediment and soil orientation surveys.

A PRELIMINARY REPORT ON THE 1987 SOIL GEOCHEMISTRY OF THE BUCK PROPERTY, CRANBROOK, BRITISH COLUMBIA

John Harrop Clifford R. Stanley

CyberQuest Exploration Systems, Ltd.
Suite 210 - 830 W. Pender St.
Vancouver, B.C. V6C 1J8

March 18, 1988

1 Introduction

This report addresses the results of the soil geochemical surveys which were undertaken during the 1987 field season on the Buck Property, Cranbrook, British Columbia by Chapleau Resources. Exploration targets on the property, which also occur in similar host lithologies and geologic settings nearby, include sediment-hosted massive-sulphide mineralization similar to that at the Sullivan Mine and precious-metal (± base-metal) quartz veins, perhaps similar to those on the east side of Moyie Lake (the St. Eugene Mine). Possibilities also exist for bulk-tonnage low-grade replacement-type Au deposits in calcareous stratigraphy of the Purcell Supergroup. A discussion of the results of these surveys is included based largely on a statistical analysis of the geochemical determinations, and based on maps of the geochemical concentrations. Recommendations for further geochemical work on the property are also presented.

Sampling was carried out by Chapleau Resources' employees during August through September 1987 and all geochemical element determinations were made by Rossbacher Laboratory, Ltd. Samples consisted of 0.5 kg of fine grained stream sediment material collected from the active bed of the streams. These were air dried and seived to -80 mesh. A 0.5 gram sub-sample was digested with a 3:1 nitric:perchloric acid attack and analysed using atomic absorption spectrometry. Elements determined include Cu, Ag, Pb, Zn and As for all soil grids. Gold was determined by a similar method, except that 10 grams of -80 mesh material was subjected to an aqua regia digestion followed by pre-concentration in MIBK. No standards were included in the analytical batches so data quality could not be determined; however, several sample sites have duplicate samples allowing a rough assessment of sample site reproducibility.

Four soil grids (Noke, BSW-1, BSW-2, BSW-3) were sampled and maps presenting the sample locations and geochemical concentrations for these samples are presented in Appendix A. The grids are, for the most part, oriented N-S with 50 m between lines and 50 m between sample sites (with the exception of the Noke Grid, which is oriented with its base line 30° east of true north). The grids are irregular because numerous grid nodes could not be sampled.

2 Statistical Analysis

2.1 Threshold Selection

A histogram and probability plot analysis (Sinclair 1974, 1976; Stanley 1987) of the geochemical concentrations was made on all of the data from the four soil grids. Output of these statistical results are presented in Appendix B.

Results indicate that all elements have subdued abundances and exhibit positively skewed distributions. Low element abundances are common in Belt-Purcell soils, even over sulphide mineralization, because of the overall low absorptive capacity of the soils (low clay and Fe-oxy-hydroxide mineral content; Stanley 1984). This allows the easy leaching of

the soluble base metals from the soils, despite high element concentrations in the source-bearing subjacent bedrock. The positive skewness of the element distributions probably results from a large number of 'background' concentrations and a small number of 'highly anomalous' concentrations which may possibly be related to economic mineralisation.

2.1.1 Copper

The Cu distribution appears to have a trimodal, log-normal form. One mode consisting of a large group of samples, exhibiting what are interpreted to be 'background' Cu concentrations and a mean of 10 ppm. Assymetric ± 1 standard deviation values about this mean are 13 and 7 ppm, respectively. A second group of samples of higher abundance can be distingushed from this 'background' group. This group of samples has a mean of 21 ppm ($\pm$ 25,17). The third group of samples has a mean of 45 ppm ($\pm$ 63,32). These concentrations are interpreted to be 'anomalous' and range up to 128 ppm Cu. The second and third groups of 'anomalous' samples may be related to lithologies containing elevated Cu concentrations or to Cu-sulphide-bearing strata. A threshold which discriminates the 'background' and 'anomalous' sample groups occurs at approximately 15 ppm, while on that discriminates the two anomalous groups occurs at 25 ppm.

2.1.2 Silver

Silver concentrations are all equal to the detection limit value of 0.2 ppm. Consequently, silver is not discussed.

2.1.3 Zinc

Zinc concentrations exhibit only moderate positive skewness and the frequency distribution of the concentrations can be modelled with a single log-normal distribution. A threshold which distinguishes possibly anomalous samples occurs at 125 ppm, a value only slightly lower than the mean plus two standard deviations value.

2.1.4 Lead

Lead concentrations also exhibit a positive skew and have an overall low abundance (with a maximum concentration of 78). Lead appears to be log-normally distributed with minor negative deviation in lower concentrations (interpreted to be due to truncation of the distribution by the detection limit). A possible second distribution on the high concentraion tail of the distribution is not of substantial enough size to obtain estimates of its mean and standard deviation values, but it can be distinguished from the 'background' group of samples by a threshold of 17 ppm (the mean plus 2 standard deviations value).

2.1.5 Gold

Gold concentraions on the Buck Property are all below or at the detection limit of 5 ppb, with one exception of 30 ppb. Consequently, the distribution of Au is not discussed.

2.1.6 Arsenic

Arsenic exhibits a bimodal normal distribution and a maximum concentration of 26 ppm. The lower mode consists of concentrations below approximately 13 ppm and probably represents 'background' sources. The higher mode, with a mean of 17 ppm and a standard deviation of 4 ppm is probably 'anomalous' and may be related to sulphide-bearing strata. A threshold of 13 ppm separates the 'anomalous' and 'background' sample groups.

3 Interpretation

Data posting plots are discussed in three sections related to the three sets of plots of the soil grid areas (BSW-1 and BSW-3 have been plooted together because of their proximity.

3.1 Noke Grid (Locations p8)

Concentrations of Au and Ag on the Noke Grid are, with the exception of one 30 ppb Au value, all equal to their respective detection limits. Copper, Pb and As exhibit anomalous concentrations along the western edge of the grid from 50 N to 100 S. In addition, high background concentrations of these elements occur in an ENE-WSW orientation which intersects this anomaly. A second, similar parallel trend occurs 75 m south of this pattern in similar elements and element concentrations. These trends may be subtle expressions of sulfide bearing structures or stratigraphy on the soil grid.

3.2 BSW Grids # 1 and # 3

The BSW-1 and BSW-3 soil grid contains only background concentrations of Au and Ag. Arsenic concentrations are above the detection limit but are not anomalous. A significant Pb anomaly, with scattered anomalous Cu and Zn concentrations within it, occurs in a zone bounded by 0 N, 100 W and 200 N 175 W. Other anomalous Zn concentrations occur on the eastern edge of the grid. The Pb anomaly may represent sulphide bearing lithologies, while the scattered Zn anomalies may represent hydromorphic dispersion of the Zn from its possible source in the Pb anomaly. The low mobility of Pb in the secondary environment, relative to Zn and Cu, supprots this interpretation.

3.3 BSW Grid # 2

The BSW-2 soil grid contains only background concentrations of Au and Ag. Scattered As and Pb anomalies occur along the base line at 250 N and 50 S. These may relflect

sampling problems. In addition, a well defined Pb anomaly occurs in the SW corner of the grid and is bounded by locations 200 S, 150 W and 0 N, 50 W and contains scattered anomalous Cu concentrations. Anomalous Zn occurs at scattered locations across, but, with one exception, not over the Pb anomaly. This geochemical signature is similar to that observed on the BSW-1 and BSW-3 soil grid and may represent a similar sulpihide mineral source.

4 Conclusions and Recommendations

Based on the results of the 1987 soil surveys on the Buck Property, several conclusions may be drawn :

- the sample size, preparation and analytical method for Au is inadequate to detect, with confidence, the presence of Au in the soils; Au is not anomalous on any of the grids;
- the preparation and analytical method for the base metals does not produce adequate contrast to confidently define samples as 'anomalous';
- two roughly E-W oriented trends defined by anomalous and 'sub-anomalous' Cu, Pb and As occur on the Noke Grid which may reflect sulphide bearing structures or stratigraphy;
- anomalous Pb zones, with scattered Cu and Zn anomalies, occur on both the BSW-1/BSW-3 and BSW-2 soil grids which may be related to massive sulphide mineralisation; the Pb could be a residual anomaly, with Cu and, particularly, Zn being leached and concentrated nearby as hydromorphic anomalies;
- given the sample density of the grids (50 m) and the observed width of the quartz veins which have been mined historically (generally less than 3 m), only a small probability (¡ 10 %) exists of sampling material derived directly from the vein material;
- no information about the effect of the glacial cover can be discerned from the data; this till could be exotic and totally unrelated to the lithologies and possible mineralization which it covers.

Based on the above conclusions, the following actions are recommended :

- an orientation survey of the soil method, using one of the known showings as a test case; from this an optimal sampling design and set of analytical procedures can be determined which will give confident detection of anomalies related to massive-sulphide, Au replacement and Au-quartz vein mineralization;

- before the commencement of any soil survey, an assessment of the glacial overburden and its effect on the detection of geochemical anomalies must be undertaken; this should include a study of the soil and overburden stratigraphy and provenence;

- follow-up of the described soil anomalies should consist of detailed soil sampling over the anomalies with the techniques defined by the orientation survey to confirm their existance;

- future soil grids should be located in known prospect areas where mineralisation has been observed or as indicated by regional stream sediment results; these should cover large areas to ensure that ore-related geochemical signatures are not missed due to glacial dispersion; small numbers of samples in soil grids are not recommended because little information regarding the relative concentration can be obtained;

- future soil grids should have nodes at 25 m or less if indicated by an orientation survey; analysis of the appropriate fraction should include an ICP multi-element (+ Hg) determination plus Au by fire assay preconcentration and atomic absorption finish; a barite specific analysis should also be included if found to be of value in the stream sediment and soil orientation surveys.

A PRELIMINARY REPORT ON THE 1987 SOIL GEOCHEMISTRY OF THE BAR PROPERTY, CRANBROOK, BRITISH COLUMBIA

John Harrop Clifford R. Stanley

CyberQuest Exploration Systems, Ltd.
Suite 210 - 830 W. Pender St.
Vancouver, B.C. V6C 1J8

March 18, 1988

1 Introduction

This report addresses the results of the soil geochemical surveys which were undertaken during the 1987 field season on the Bar Property, Cranbrook, British Columbia by Chapleau Resources. Exploration targets on the property, which also occur in similar host lithologies and geologic settings nearby, include sediment-hosted massive-sulphide mineralization similar to that at the Sullivan Mine and precious-metal (± base-metal) quartz veins, perhaps similar to those on the east side of Moyie Lake (the St. Eugene Mine). Possibilities also exist for bulk-tonnage low-grade replacement-type Au deposits in calcareous stratigraphy of the Purcell Supergroup. A discussion of the results of these surveys is included based largely on a statistical analysis of the geochemical determinations, and based on maps of the geochemical concentrations. Recommendations for further geochemical work on the property are also presented.

Sampling was carried out by Chapleau Resources' employees during August through September 1987 and all geochemical element determinations were made by Rossbacher Laboratory, Ltd. Samples consisted of 0.5 kg of fine grained stream sediment material collected from the active bed of the streams. These were air dried and seived to -80 mesh. A 0.5 gram sub-sample was digested with a 3:1 nitric:perchloric acid attack and analysed using atomic absorption spectrometry. Elements determined include Cu, Ag, Pb and As for all soil grids and lines. Zn was determined for only two of the four soil lines. Gold was determined by a similar method, except that 10 grams of -80 mesh material was subjected to an aqua regia digestion followed by pre-concentration in MIBK. No standards were included in the analytical batches so data quality could not be determined; however, several sample sites have duplicate samples allowing a rough assessment of sample site reproducibility.

Three soil grids (Quartz Pit/Horseshoe, Gossan Hill, BL-00/Float Train) and 4 soil lines (BL-1, BL-2, BL-5, BL-6) were sampled and maps presenting the sample locations and geochemical concentrations for these samples are presented in Appendix A. The grids are, for the most part, oriented N-S with 50 m between lines and 50 m between sample sites. The grids are irregular because numerous grid nodes could not be sampled. Soil lines are oriented in two orientations. BL-1 and BL-2 are parallel to each other, oriented roughly E-W and straddle both sides Palmer Bar Creek. BL-5 and BL-6 are also parallel, oriented roughly N-S, and have their northern termini along the south side of Palmer Bar Creek near those of soil lines BL-1 and BL-2. None of the soil lines are precisely straight, but all have been plotted on the same set of maps.

2 Statistical Analysis

2.1 Threshold Selection

A histogram and probability plot analysis (Sinclair 1974, 1976; Stanley 1987) of the geochemical concentrations was made on all of the data from the three soil grids and four soil

lines. Output of these statistical results are presented in Appendix B.

Results indicate that all elements have subdued abundances and exhibit positively skewed distributions. Low element abundances are common in Belt-Purcell soils, even over sulphide mineralisation, because of the overall low absorptive capacity of the soils (low clay and Fe-oxy-hydroxide mineral content; Stanley 1984). This allows the easy leaching of the soluble base metals from the soils, despite high element concentrations in the source-bearing subjacent bedrock. The positive skewness of the element distributions probably results from a large number of 'background' concentrations and a small number of 'highly anomalous' concentrations which may possibly be related to economic mineralisation.

2.1.1 Copper

The Cu distribution appears to have a trimodal, log-normal form. One mode consisting of a large group of samples, exhibiting what are interpreted to be 'background' Cu concentrations and a mean of 15 ppm. Assymetric ±1 standard deviation values about this mean are 25 and 9 ppm, respectively. A second group of samples of higher abundance can be distinguished from this 'background' group. This group of samples has a mean of 70 ppm (± 94,54). The third group of samples has a mean of 194 ppm (± 280,136). The higher two modes have concentrations interpreted to be 'anomalous'. The second and third groups of 'anomalous' samples may be related to lithologies containing elevated Cu concentrations or to Cu-sulphide-bearing strata. A threshold which discriminates the 'background' and 'anomalous' sample groups occurs at approximately 40 ppm, while on that discriminates the two 'anomalous' groups occurs at 110 ppm.

2.1.2 Silver

Silver concentrations are positively skewed and range up to 4.0 ppm. A threshold of 0.6 ppm (3× the detection limit of 0.2 ppm) can be used to distinguish 'background' from 'anomalous' concentrations.

2.1.3 Zinc

Zinc concentrations exhibit only moderate positive skewness and the frequency distribution of the concentrations can be modelled with a mixture of three normal distribution. The lowest mode has a mean of 59 ppm and standard deviation of 13 ppm and probably represents 'background' concentrations. The middle mode, with a mean and standard deviation of 92 and 15 ppm, may reflect 'background' or 'anomalous' concentrations. The highest mode, with a mean concentration of 137 ppm (± 20 ppm) is classified as 'anomalous'. A threshold which distinguishes the lowest mode of samples from the middle mode occurs at 70 ppm, and the threshold between the higher two modes occurs at 120 ppm.

2.1.4 Lead

Lead concentrations also exhibit a positive skew and have an overall low abundance (with a maximum concentration of 116). Lead appears to be log-normally distributed with minor negative deviation in lower concentrations (interpreted to be due to truncation of the distribution by the detection limit). A possible second distribution on the high concentraion tail of the distribution is not of substantial enough size to obtain estimates of its mean and standard deviation values, but it can be distinguished from the 'background' group of samples by a threshold of 32 ppm (the mean plus 2 standard deviations value).

2.1.5 Gold

Gold concentrations on the Bar Property are extremely positively skewed with a maximum value of 130 ppb. Since 98 % of the samples report concentrations of 5 or 10 ppb, 'anomalous' concentrations can be considered those greater than 15 ppb.

2.1.6 Arsenic

Arsenic exhibits a bimodal normal distribution and a maximum concentration of 60 ppm. The lower mode consists of concentrations below approximately 18 ppm and probably represents 'background' sources. The higher mode, with a mean of 17 ppm and a standard deviation of 4 ppm is probably 'anomalous' and may be related to sulphide-bearing strata. A threshold of 18 ppm separates the 'anomalous' and 'background' sample groups.

3 Interpretation

Data posting plots are discussed in five sections related to each of the three soil grid areas and a combined summary of the soil line results. (Locations p.9)

3.1 Quartz Pit/Horseshoe Grid

Highly 'anomalous' Cu concentrations occur alonf the base and 50 W lines. These define a distinct 'anomalous' zone. 'Anomalous' Ag, Pb, Au and As occur SE of this zone in an irregular pattern, but, significantly, not over it. This may suggest that the element distribution pattern is largely a function of secondary dispersion processes. The high concentrations of most elements on this grid do suggest that presence, somewhere, of a sulphide bearing source.

3.2 Gossan Hill Grid

'Anomalous' Cu concentrations occur in two well defined anomalies on the Gossan Hill soil grid. These occur at 100 N, 75 W to 100 N, 200 W (plus at site 200 N, 150 W) and at 300 N, 100 E to 300 N, 250 E. Scattered 'anomalous' Ag, Au, Pb and As also occur in

these sites. These 'anomalies' may be related to sulphide bearing lithologies beneath the soil grid.

3.3 BL-00/Float Train Grid

Generally, 'anomalous' concentrations of the elements do not occur on the BL-00/Float Train soil grid. No distinct 'anomalous' zone is defined by any element; however, higher 'background' concentrations of Cu occur along the two northern-most grid lines. Gold concentrations are all at the detection limit and Ag concentrations cannot be distinguished from its detection limit.

3.4 Soil Lines 1, 2, 5 and 6

Soil Lines 1, 2, 5 and 6 define several suspected 'anomalous' zones. Sightly 'anomalous' As, Pb and Zn concentrations occur at several locations along lines 5 and 6. These do not generally overlap each other, and thus may represent differential dispersion of As, Pb and Zn. Samples from all soil lines report no 'anomalous' Ag and Cu concentrations, but Au several anomalies occur along line 1 which may deserve follow-up.

4 Conclusions and Recommendations

Based on the results of the 1987 soil surveys on the Bar Property, several conclusions may be drawn :

- the sample size, preparation and analytical method for Au is inadequate to detect, with confidence, the presence of Au in the soils;
- the preparation and analytical method for the base metals does not produce adequate contrast to confidently define samples as 'anomalous';
- 'anomalous' zones of Pb, Zn, As and sometimes Ag and Au occur on the Gossan Hill and Quartz Pit/Horseshoe grids and along several of the soil lines; geometries of these zones suggest that they are a product of differential dispersion;
- given the sample density of the grids (50 m) and the observed width of the quartz veins which have been mined historically (generally less than 3 m), only a small probability ($\downarrow$ 10 %) exists of sampling material derived directly from the vein material;
- no information about the effect of the glacial cover can be discerned from the data; this till could be exotic and totally unrelated to the lithologies and possible mineralization which it covers.

Based on the above conclusions, the following actions are recommended :

- an orientation survey of the soil method, using one of the known showings as a test case; from this an optimal sampling design and set of analytical procedures can be determined which will give confident detection of anomalies related to massive-sulphide, Au replacement and Au-quartz vein mineralisation;
- before the commencement of any soil survey, an assessment of the glacial overburden and its effect on the detection of geochemical anomalies must be undertaken; this should include a study of the soil and overburden stratigraphy and provenence;
- follow-up of the described soil anomalies should consist of detailed soil sampling over the anomalies with the techniques defined by the orientation survey to confirm their existance;
- future soil grids should be located in known prospect areas where mineralisation has been observed or as indicated by regional stream sediment results; these should cover large areas to ensure that ore-related geochemical signatures are not missed due to glacial dispersion; small numbers of samples in soil grids are not recommended because little information regarding the relative concentration can be obtained;
- future soil grids should have nodes at 25 m or less if indicated by an orientation survey; analysis of the appropriate fraction should include an ICP multi-element (+ Hg) determination plus Au by fire assay preconcentration and atomic absorption finish; a barite specific analysis should also be included if found to be of value in the stream sediment and soil orientation surveys.

REPORT ON THE 1987 STREAM SEDIMENT GEOCHEMISTRY OF THE MORGAN, BUCK AND BAR PROPERTIES, CRANBROOK, BRITISH COLUMBIA

John Harrop Clifford R. Stanley

CyberQuest Exploration Systems, Ltd.
Suite 210 - 830 W. Pender St.
Vancouver, B.C. V6C 1J8

March 18, 1988

1 Introduction

This report addresses the results of the stream sediment silt geochemical survey which was undertaken during the 1987 field season on the Morgan, Buck and Bar Properties, Cranbrook, British Columbia by Chapleau Resources. Exploration targets on the property, which also occur in similar host lithologies and geologic settings nearby, include sediment-hosted massive-sulphide mineralization similar to that at the Sullivan Mine and precious-metal (± base-metal) quartz veins, perhaps similar to those on the east side of Moyie Lake (the St. Eugene Mine). Possibilities also exist for bulk-tonnage low-grade replacement-type Au deposits in calcareous stratigraphy of the Purcell Supergroup. A discussion of the results of this survey is included based largely on a statistical analysis of the geochemical determinations, and based on maps of the geochemical concentrations. Recommendations for further geochemical work on the property are also presented.

Sampling was carried out by Chapleau Resources' employees during August through September 1987 and all geochemical element determinations were made by Rossbacher Laboratory, Ltd. Samples consisted of 0.5 kg of fine grained stream sediment material collected from the active bed of the streams. These were air dried and seived to -80 mesh. A 0.5 gram sub-sample was digested with a 3:1 nitric:perchloric acid attack and analysed using atomic absorption spectrometry. Elements determined include Cu, Ag, Zn, Pb, and As for all samples. Gold was determined by a similar method, except that 10 grams of -80 mesh material was subjected to an aqua regia digestion followed by pre-concentration in MIBK. No standards were included in the analytical batches so data quality could not be determined; however, almost 90 % of the sites were sampled in duplicate, allowing an assessment of sample site reproducibility.

Seven major stream drainages were sampled at an irregular interval averaging approximately 500 m. These drainages include the Wuho, Negro, Noke, London, Waverley, Wuhun Creeks and an unnamed stream (abbreviated 'Wo', 'Ng', 'Nk', 'Ld', 'Wv', 'Wu' and 'Ck', respectively). Maps presenting the sample locations and geochemical concentrations for these samples are presented in Appendix A.

2 Statistical Analysis

2.1 Error Analysis

Evaluation of the sample site reproducibility based on the Thompson-Howarth method using duplicate samples (Thompson and Howarth 1973, 1976a, 1976b, 1978; Thompson 1978) was made. Output from the analysis are presented in Appendix B. Because of the large number of detection level values for Ag and Au, the Thompson-Howarth analysis could not be performed on these elements. Results for Cu, Zn and As indicate that they have relative site reproducibility errors of approximately 5 %, while Pb has a relative site reproducibility error of approximately 10 %. These levels of error in a site replicate context are considered excellent for geochemical determinations.

2.2 Threshold Selection

A histogram and probability plot analysis (Sinclair 1974, 1976; Stanley 1987) of the geochemical concentrations was also made on all of the stream sediment data. Output of the statistical results are presented in Appendix C.

Results indicate that all elements exhibit positively skewed distributions. The positive skewness of these element distributions probably occurs because the samples have a large number of 'background' concentrations and a small number of 'highly anomalous' concentrations which may be derived from economic mineralization.

2.2.1 Copper

The Cu distribution appears to have a bimodal, normal form. One mode, consisting of a large group of samples and exhibiting what are interpreted to be 'background' Cu concentrations, has a mean of 15 ppm and a standard deviation of 10 ppm. A second group of samples of higher abundance can be distingushed from this 'background' group. Concentrations from this group are interpreted to be 'anomalous' and range up to 198 ppm Cu. This second group of 'anomalous' samples may be related to lithologies containing elevated Cu concentrations or to Cu-sulphide-bearing strata. A threshold which discriminates the 'background' and 'anomalous' sample groups occurs at approximately 35 ppm.

2.2.2 Silver

Silver concentrations are positively skewed and have a maximum value of $>$ 100 ppm. The low number of reported concentration values does not allow rigorous statistical evaluation of the Ag data. Concentrations in excess of (an arbitrarily selected) 3$\times$ the detection limit of 0.2 ppm are thus considered anomalous.

2.2.3 Zinc

Zinc concentrations are extremely positively skewed with a maximum concentration of $>$ 10000 ppm. The distribution appears to bimodal log-normal. A 'background' group of samples has a mean of 62 ppm and assymetric ± 1 standard deviation values of 87 and 44 ppm, respectively. An 'anomalous' group of samples can be distinguished from these 'background' samples with a threshold of 90 ppm.

2.2.4 Lead

Lead concentrations also exhibit a positive skew and have a maximum concentration of $>$ 10000 ppm. Lead appears to be bimodal, log-normally distributed with minor negative deviation in lower concentrations (interpreted to be due to truncation of the distribution by the detection limit). The 'background' group of samples has a mean of 11 ppm and assymetric ± 1 standard deviation values of 24 and 5 ppm, respectively. The 'background'

sample group can be distinguished from the 'anomalous' group of samples with a threshold of 52 ppm.

2.2.5 Gold

Gold exhibits a positively skewed distribution consisting of samples with 'background' concentrations of 5 ppb and samples with 'anomalous' concentrations above 5 ppb. While probably distributed poisson, this distribution can be approximated by a mixture of two log-normal distributions. Since gold probably exists largely in its native form in these stream sediments, the 'background' sample group can be considered to be those samples where the analyzed sub-sample contained no gold nuggets (resulting in a reported concentration of 5 ppb). The 'anomalous' group of samples can be considered to consist of those samples where the analyzed sub-sample contained at least one grain of gold (yielding concentrations greater than 5 ppb).

Unfortunately, while any of the 0.5 kg samples may contain numerous gold nuggets, the 10 gram sub-sample split from it **may not contain any**. Furthermore, hydraulic effects from the stream water flow regime may have acted to concentrate or deplete sample sites in the creeks, adding further inaccuracy to the sampling. As a result, given the relatively small amount of sample which was collected and even smaller amount that was actually analyzed, samples from sites which actually contain gold may report 5 ppb concentrations. Little confidence may be placed on samples reporting concentrations of 5 ppb as representing stream locations not containing Au. Nonetheless, a threshold of 10 ppb distinguishes the 'background' from 'anomalous' samples.

2.2.6 Arsenic

Arsenic exhibits a trimodal normal distribution and relatively high overall concentrations (cf. Stanley 1984). The lowest mode has a mean of 5 ppm with a standard deviation of 4 ppm. The middle mode has a mean of 17 ppm, a 4 ppm standard deviation, and can be distinguished from the lower mode with a threshold of 11 ppm. The highest mode, with a 31 ppm mean and 7 ppm standard deviation is probably 'anomalous' and may be related to sulphide-bearing strata. A threshold of 21 ppm separates this 'anomalous' group from the two, probably, 'background' sample groups.

3 Interpretation

Interpretive symbolic maps of the stream sediment data are presented in Appendix D. Samples with average replicate concentrations exceeding the threshold are indicated by large circles while those average concentrations less than the threshold are indicated with small circles. These plots suggest that the primary area of interest lies in the Wuho Creek drainage and specifically on the north side of the main stream. On this stream, four distinct stream sediment anomalies exist in several elements.

The most western anomaly is defined by sample site Wo-6, where highly anomalous concentrations of Cu, Pb, Zn, Ag, Au and As are observed. For Pb, Zn and Ag, the concentrations exceed the maximum determinable concentrations using geochemical methods of 10000, 10000 and 100 ppm, respectively. These extremely high concentrations and the accompanying high replicate disparity suggests that detrital sulphides are present in the stream sediment samples and that these comprise a major portion of the element concentration. Furthermore, these observations may suggest that the source of the anomaly may be located only a small distance north of the sample site.

Sample Wo-3 probably represents downstream dispersion from the Wo-6 anomaly, and the proximity of 'anomalous' sample Wo-7 to Wo-6 suggests that the source of this anomaly may be on the west side of the stream sampled by Wo-6. Anomalous Zn concentrations at sites Wo-2, Wo-4 and Wo-7 may represent more extensive hydromorphic dispersion due to the generally higher mobility of Zn in the secondary environment. Alternatively, these samples may be anomalous due to organic concentration of Zn in a boggy reach of the drainage.

Downstream (to the east) of this site is another anomaly defined by sample Wo-8. It is clearly not part of the dispersion train from the Wo-6 anomaly and related to another source of high element concentration because of the presence of non-anomalous sample Wo-1 immediately upstream of it. It also has anomalous concentrations in Cu, Pb, Zn, Ag, Au and As, suggesting a source for this anomaly somewhere between Wo-8 and Wo-1.

Sample Wo-20 defines an anomaly of a possibly different type. It has anomalous concentrations in all of the elements anomalous in samples Wo-3 and Wo-8, except for Au. The source of this anomaly is probably north of the sample site, and dispersion from this anomaly is probably represented in samples Wo-21 and Wo-22.

The last anomaly observed considered of primary importance is defined by anomalous concentrations of Cu, Pb, Zn, Ag and As in sample Wo-23. It, thus, has a geochemical signature similar to the anomaly defined by sample Wo-20. Dispersion downstream from this anomaly is probably represented by sample Wo-24, and its source is probably to the north of the sample site.

Several other anomalies also exist on the property. These consist mainly of single point anomalies in several different elements and all are defined by element concentrations which are not significantly in excess of the threshold value, given the observed relative error. One exception exists.

Near the head of Noke Creek, a coherent set of anomalous Zn concentrations occur (samples Nk-12, Nk-13, Nk-14 and Nk-16). While these may represent organic concentration of Zn in a boogy reach of the drainage, the stream immediately west of this site (containing 3 lakes) has a multi-point Cu anomaly. In addition, anomalous Ag and As occur at site Nk-16. The similarity of this anomaly to the one defined by sample Wo-6 augurs its importance.

4 Conclusions and Recommendations

Based on the results of the 1987 stream sediment survey, several conclusions may be drawn :

- the size of the stream sediment samples and analytical method is inadequate to detect, with confidence, the presence of Au in the streams;
- four distinct geochemical anomalies occur on Wuho Creek which may potentially be related to massive sulphide mineralization similar to that observed at the Sullivan Mine;
- these anomalies may be of two types: those that contain anomalous Au (the two to the west), and those that don't; alternatively, these anomalies may all be similar and the sampling inadequacies for Au (described above) may have contributed to the non-detection of Au in the two eastern anomalies;
- a fifth anomaly exists near the head of Noke Creek which may be similar to those observed on Wuho Creek;
- given the sample density on the streams and the length of the dispersion trains observed below the anomalies on Wuho Creek, only one or two samples actually record anomalous concentrations; as a result, anomalies may exist between sample sites which are spaced more than 500 m apart, **and thus may go undetected.**

Based on the above conclusions, the following actions are recommended :

- an orientation survey of the stream sediment collection method, using one of the observed anomalies on Wuho Creek as a test case; from this an optimal sampling design and set of analytical procedures can be determined which will give confident detection of anomalies related to both massive-sulphide and Au-quartz vein mineralization;
- a detailed stream sediment survey of all streams on the property (based on the above described orientation survey) at one sample every 250 m along the stream and above all forks; this should include a multi-element (+ Hg) ICP analysis of the silt fraction **plus** a non-magnetic and magnetic heavy liquid separation of up to 5 kg of fine grained stream sediment; analysis of Au should be by fire assay pre-concentration and atomic absorption; a barite specific determination should be included; this survey should take place immediately after spring run-off to avoid hydraulic re-distribution of heavy minerals;

- anomalous zones discovered by the 1987 stream sediment survey should be confirmed with a follow-up detailed stream sediment survey according to the design defined by the stream sediment orientation survey;
- before the commencement of any subsequent soil survey, an assessment of the glacial overburden and its effect on the detection of geochemical anomalies **must** be undertaken; this should include a study of the soil/overburden stratigraphy and provenence and a search for the optimal sample design in a soil orientation survey;
- all confirmed stream sediment anomalies should be intensively prospected and covered with an extensive soil grid with nodes at 25 m centers; analysis of the -80 mesh fraction should include an ICP multi-element (+ Hg) determination plus Au by fire assay pre-concentration and atomic absorption finish; a barite specific analysis should also be included if found to be of value in the stream sediment and soil orientation surveys.
