0.0 SUMMARY AND RECOMMENDATIONS

Erik Ostensoe and Thomas E. Lisle completed a program of prospecting, mapping and sampling at Hatchau Lake, north of Telegraph Creek, B. C., during July, 1995. Strong hydrothermal alteration in a major fracture zone was investigated at "Gossan" Creek and fracture controlled gold-sulphide mineralization was sampled at "Hoey" Creek.

Gossan Creek is believed to represent a high level alteration suite imposed on sheared and brecciated arenaceous rocks that may be situated on the flanks of a stratovolcano. Substantial gold and copper values were obtained from the Hoey Creek area where gabbroic rocks are fractured and sheared. Other mineralized areas were examined in less detail.

Further work in the Hatchau Lake area is strongly recommended. The broad zone of alteration at Gossan Creek should be further mapped and sampled. Mineralogical studies should be completed in order to determine if the zone represents a weakly mineralized capping overlying a classic epithermal environment that may host a bonanza-type gold deposit. The Hoey mineral zones should be mapped, possibly using plane-table methods, to determine if mineralization is epithermal or volcanogenic in origin. The remainder of the Hat and Cap claims should be mapped in reconnaissance fashion with particular efforts directed to a search for evidence of porphyry copper deposit type environments.

1.0 INTRODUCTION

1.1 Introduction

A program of prospecting, geological mapping, soil sampling and rock chip sampling was completed on the Hat property at Hatchau Lake, north of Telegraph Creek, B. C. in the period July 9 - July 29, 1995. Work was done by Mssrs. Erik Ostensoe, P. Geo. and T. E. Lisle, P. Eng., geologists, with partial but substantial financial assistance provided by the Prospectors Assistance Program of the Ministry of Energy, Mines and Petroleum Resources, reference no. 95-96-P067.

Work was done under terms of Section 10, Mines Act, and Approval No. SM 1-95-0101459-147 (letter - Darryl Hanson, P. Eng., Inspector of Mines).

This report summarizes the 1995 work program. A discussion of the project is presented and further work is recommended.

1.2 Location and Access

The Hat Project is located in Atlin M. D. at Hatchau Lake, 40 km north of Telegraph Creek and 95 km southwest of Dease Lake, British Columbia (Figure 1).

Access to the project in 1995 was by float-equipped Otter aircraft from Dease Lake. The road that connects the Dease Lake-Telegraph Creek road to the Golden Bear mine passes about eight kilometres south of the property and may in future facilitate work in the area.

1.3 Property

The Hat Project comprises 59 claim units in four four-post and two two-post claims as detailed in Table 1 and illustrated in Figure 2.

Claim	Record No.	Size	Units	Owner	Expiry Date
Bob 1	338097	5 X 4	20	E. Ostensoe	July 12, 1996

TABLE 1. Claims - Hat Project

1.4 History

The gossaned carbonate alteration zones prominently displayed along the hillsides north of the Kennicott - Hatchau Lake and Hackett River valley undoubtedly have attracted the attention of prospectors since the earliest explorations of the area. The Hoey showings may have been discovered in 1963 by Frank Hoey, a prospector from eastern Canada with financing provided by a syndicate of mining companies.

Atled Resources Ltd., Colorado Corporation (a unit of King Resources), Newconnex Canadian Exploration Ltd., and United Cambridge Resources Ltd., a VSE junior company, variously carried out work on porphyry copper prospects near the west end on the valley in the period 1968 to 1988. Utah Mines Ltd. explored claims (Ski 1 - 6 claims) in the immediate Hat Project

area in the period 1977 through 1980 (MEMPR assessment report 6835), established an 144 kilometre line grid, conducted induced polarization and magnetic surveys, bulldozer trenching, and analysed almost 2000 soil samples for copper. More recent work in the area known to the writer includes airborne magnetic and VLF-EM surveys by United Cambridge Mines Limited in the Hatchau Lake area during 1987 and regional scale airborne surveys in the Hackett River valley directed by Golden Ring Resources Ltd. during 1991 (MEMPR assessment report 22100).

2.0 GEOLOGY OF THE HATCHAU LAKE AREA

2.1 Introduction

The Hatchau Lake area is located at the southwest edge of the Nahlin Plateau, a sub-division of the Stikine Plateau in the Intermontane Belt of northwestern British Columbia, immediately east of the Coast Mountains. It is south of Level Mountain, a Plio-Pleistocene plateau volcano, and north and west of the Grand Canyon of Stikine River. Elevations vary from 625 to 1200 metres above sea level. Streams flow westerly via Hackett River into Sheslay River, a tributary of the Taku River system.

Prevailing structural trends are those of the Cordillera - northwest with strong northerly disruptions. Dominant lithologies are pre-Triassic age Cache Creek formation sedimentary rocks and Late Triassic-Early Jurassic age Stuhini Group volcaniclastic rocks. Granitic intrusive rocks, including the Kaketsa stock ten kilometres west of Hatchau Lake, have been dated as Late Triassic age.

Stuhini Group rocks are related to Takla and Nicola Group formations that are extensive in British Columbia and that are hosts to most of Canada's porphyry copper deposits. Low grade copper deposits have been explored in the vicinity of the Kaketsa stock, at Dick Creek and at Copper Creek in the Sheslay area and, in the Hat Project area, north of Hatchau Lake. Gold occurrences include the Wolverine deposit that has been explored at Kilometre 44, eight kms south of Hatchau Lake, and at Hoey, north of that lake. Large brightly coloured carbonate altered zones that occur along the east-west valley of Hackett River appear to be related to north-trending structural zones. Superficial Quaternary gravel and clay deposits present along the north side of the valley occasionally exhibit depths in excess of three metres.

2.2 Geology

No systematic geological mapping was undertaken as part of the 1995 program of work and the following observations are in large part based on previously recorded information, in particular the work of Utah Mines Ltd. (MEMPR assessment reports 6835, 7482).

The Hat Project area lies at the south edge of the Plio-Pleistocene age Level Mountain volcano. Massive dark grey to black basaltic flows from that source are present in the northern parts of the claims. The principal Stuhini Group rocks are porphyritic augite andesites, with basalt, chert, siltstone and tuffaceous sedimentary members. Alteration in many variations is widespread, comprising pyritization, chloritization, argillization, and, to a limited extent, potash feldspathization. Monzonitic intrusive rocks are present in the uplands immediately north of Hatchau Lake where they were excavated in bulldozer trenches and in small outcroppings near the point of emergence of Hoey Creek into the Hatchau Lake valley. Small amounts of disseminated magnetite, pyrite and chalcopyrite accompany the intrusions.

Carbonate altered rocks exposed in "Gossan" Creek northwest of Hatchau Lake are strongly fractured sedimentary units, principally tuffs, siltstone, claystone and probably rocks of primary carbonate origin.

A broad north-striking fault zone occupies the deeply incised valley of "Gossan" Creek where it is exposed throughout over a distance of one kilometre, weakening and disappearing at the canyon headwall near where the transition from sedimentary terrain to igneous rocks occurs.

Air photographs that cover the Hatchau Lake area show strong linear features: both northwesterly, conforming in a general way not only to the principal drainage direction but also to Cordilleran trends, and northerly, approximating the trends of the Shesley River- Dudidontu River valley, a few kilometres to the west, and Beatty Creek to the east. Relating such structures to the fundamental fractures that support the major volcanoes in the regional is an intriguing but wholly speculative exercise. Similarly speculative is the concept that the area of work is one the flank of a broad stratovolcano that has existed through considerable geologic time and that now forms the platform on which the Level Mountain volcano has been built.

The Wolverine gold prospect, located eight kilometers south of the Hat project, and explored by Homestake in 1989-91, is located in proximity to a north striking lineament that, if projected, would pass through the project area and, incidentally, into the heart of Level Mountain.

2.3 Magnetics and VLF-EM Data

The airborne magnetometer and VLF-EM survey of the Moon claims, predecessors of the Hat project claims, in 1987 confirmed that the southern portion of the claims is mainly sedimentary whereas the northern portion is mainly volcanic in character (Mark and Cruikshank, 1987). The geophysicists, on the basis of magnetic patterns, postulated that a large gabbroic-diorite stock is present in the northwest quadrant of the project area. They also postulated from VLF-EM data, the presence in the same general area of a sulphide-bearing shear zone with strike direction (northerly) similar to that of the "Gossan" Creek shear zone. However, the locations of neither the latter nor the Hoey zone were obvious from their data.

3.0 1995 WORK PROGRAM

3.1 Introduction

Erik Ostensoe, P. Geo. and T. E. Lisle, P. Eng., in spring, 1995, applied to the Prospectors Assistance Program for funding in support of a proposed program of prospecting work on the Hat Property. The application was successful and work was undertaken in the period July 9 - July 29, 1995. The prospectors were visited in the field on July 25 by P. J. Wojdak, P. Eng., district geologist, Ministry of Energy, Mines and Petroleum Resources.

Work included prospecting and reconnaissance on the "Gossan" Creek and Hoey showings, geochemical sampling and rock chip sampling. Crude survey grids and traverses were established by belt-chain and compass methods. One hundred and twenty-four samples were taken and subsequently were analysed by induced coupled plasma methods for 30 elements and by graphite furnace/atomic absorption for gold. Eighteen soil samples taken between 10 W and 19W on line 8+00 North were not analysed but are in storage for possible future analysis.

3.2 Field Work

Mssrs. Ostensoe and Lisle travelled to Dease Lake, B.C. by vehicle (1795 km) and thence to Hatchau Lake by chartered aircraft operated by BC Yukon Air Service. A tent camp was set up on the shore of the lake. The constant and annoying attention of a black bear necessitated innovative methods to protect the food supply but even so the sleeping tent was slashed and almost totally destroyed. Work (Figure 2) was divided between the "Gossan" Creek zone where the brightly orange-coloured canyon walls highlight a zone of intense shearing and accompanying

carbonate alteration and the Hoey showings where a zone of gold-bearing sulphide mineralization has been shredded by a complex of fractures. Some secondary areas of interest were also checked. The prospectors left the field site on July 27, 1995.

A grid of soil samples was established across the canyon of "Gossan" Creek and, following prospecting, several of the mineral zones were chip sampled (Figures 3 and 4). Old trenches at the Hoey site were refreshed, enlarged, mapped and sampled in detail and adjacent areas were prospected (Figures 5 and 6). Two nearby, possibly related, mineralized areas were investigated: a bulldozer trench about 500 metres north of Hoey, and the lower canyon of "Big" Creek, the stream that enters Kennicott Lake-Hatchau Lake valley immediately east of Hoey (Figure 7).

Rock chip samples were placed in plastic bags which were identified by numbered paper tags. Soil samples were taken from 'B' and 'C' horizon soils and placed in standard kraft paper envelopes identified by marker pen notations. Sample details were recorded on prepared data sheets (Appendix 1). Certain samples from non-critical areas were not analysed: due in part to financial limitations but also pending receipt of other, presumed more pertinent, analytical data.

Thirty-three rock chip samples, 75 soil samples, 2 stream sediment samples, and 14 talus fines samples were submitted to Acme Analytical Laboratories Ltd. 0.5 gram samples of dried soil or crushed rock materials were digested in hot aqua regia and analysed for 30 elements by standard ICP-ES (induced coupled plasma emission spectrometry) methods. Gold determinations were performed on 10 gram samples with aqua regia digestion, MIBK extraction and graphite furnace atomic absorption analysis. Gold detection limit by this method is 2 ppb.

Geochemical analysis certificates are included in Appendix 2 of this report.

3.3 WORK IN "GOSSAN" CREEK AREA

Eighteen man-days were devoted to work in the "Gossan" Creek area. A series of east-west grid lines were extended across parts of the canyon and where terrain and conditions permitted, soil samples were taken at 50 metre intervals (Figures 3 and 4). Line 8+00S was extended westerly to 19+00W where it was ended close to Hackett River. Soil samples from 10+00 W to 19+00W on Line 8+00S were not analysed, and, pending further financing, remain in storage.

"Gossan" Creek flows southerly in a steep, narrow canyon into the Hackett River valley where it disperses into the gravel beds. The canyon is developed in a series of bedded rocks, mostly tuffs, that are strongly sheared. Intense silica and carbonate alteration accompanies mylonitized and gougy strands of a broad fault zone and several areas of carbonate-cemented

breccia were noted. Similar brightly coloured altered and brecciated rocks were found along the hillside for a distance of one kilometre west of the canyon. Rocks to the north in the canyon are more competent and are somewhat less intensely faulted, perhaps in response to proximity to the transition that is believed to exist northerly from sedimentary rocks into primarily volcanic and intrusive rocks that underlie the upland terrain.

Dominant rock types are andesite, which is present as bedded tuff and as more massive beds, possibly flows, and various sedimentary rocks. Finely banded tuffs and narrow layers of chert are indicative of a sedimentary environment and the abundance of calcareous alteration minerals suggest that limestones or limey sediments may have been present but were absorbed and re-distributed by faulting and shearing.

Small amounts of monzonite are present in the upper part of "Gossan" Creek canyon and large areas of flatter ground to the north are known to be of similar intrusive character. It is speculated that the small occurrences found in the canyon are slices caught up in the faulting. The outcroppings of intrusives were altered approximately to the same degree as were nearby bedded rocks.

Figure 3 illustrates several zones of shearing and faulting, the most dominant directions of which are northwest and northeast. A gently northwest dipping, northeast striking, zone of shearing in the vicinity of 3+50S/7+75W is consistent with gold and copper geochemical patterns that are suggestive of the presence of layered structures that have been disrupted by steeper angled north-trending faulting.

Figure 4 illustrates partial geochemical data from the "Gossan" Creek area. Only gold and copper values are shown and other analyses are available from geochemical certificates included in Appendix 2 of this report. Further study of the analyses is required, with particular attention to data for cobalt, arsenic, and zinc. Manganese is present in significant amounts.

Eight rock chip samples from "Gossan" Creek canyon area were analysed for 30 elements plus gold. Locations of samples are plotted on Figure 3 and sample numbers have been underlined. Rock analyses returned low gold and copper values.

A compilation of all available data from previous work in the Hatchau Lake area is in progress but to date no conclusions regarding the potential of the "Gossan" Creek area have been reached. The strong overprinting of ferruginous carbonate and argillic alteration is similar to that found in acid sulphate clay-silica cappings in the upper levels of epithermal systems, as described by Panteleyev (in Ore Deposit Models, Geoscience Canada, 1988) and by Buchanan (presentation, 1980 Geoscience Forum, Whitehorse). Substantial gold deposits may be expected to occur at shallow depths below such environments.

3.4 WORK IN HOEY SHOWINGS AREA

Fourteen man-days were directed to work in the vicinity of the "Hoey" showings. This area is located along the east side of a steep-walled canyon formed by the incision of Hoey Creek into the south-facing slope of the Hatchau Lake-Kennicott Lake valley.

First known work in this area is believed to have been done in 1963. Several small follow-up programs of work are evidenced by several small hand-dug trenches developed on mineralized structures in strongly fractured dark rocks of volcanic origin. The mineralized structures are narrow layers of deeply oxidized specular hematite, pyrite, and minor chalcopyrite. Secondary minerals are present to the depth of the trenches.

Work in 1995 included refreshing, deepening and extending the old trenches and new digging on other nearby showings. A simple belt-chain and compass survey was established over the mineralized area as a basis for taking chip samples from the various strands of metallic minerals (Figure 5). Twelve chip samples were submitted for analyses.

A belt-chain and compass traverse from the north end of the trenched area followed the east rim of the canyon, crossed the creek to the west side and then ran southerly (Figure 6). The purpose was to provide a crude means of relating samples from the "Hoey West" area to the main area. Four chip samples were taken from a prominent carbonate bluff located close to the creek bottom. Three additional samples were taken from narrow strands of mineralization located on the lower east side of the canyon. Sample no. 4878 was taken from a shear zone exposed in an old roadcut situated about 260 metres north of the north end of the traverse ("Hoey North"). Figure 7 illustrates a line of talus fines samples that were taken from the west side of "Big" Creek. Big Creek occupies a valley located about 600 metres east of the Hoey area.

Samples at the main Hoey area were taken from nine different strands of mineralization, all of which had similar characteristics but the degree of shearing and oxidation varied considerably. Gold analyses varied from 220 to 8110 ppb and copper values, from 779 to 22041 ppm. The carbonate bluff west of Hoey Creek ("Hoey West") returned lower gold and copper values than did the main area, from 40 to 820 ppb gold, and 1977 to 7762 ppm copper. The "Hoey North" sample returned 3580 ppb gold and 3638 ppm copper. Talus fines samples from "Big Creek", east of Hoey, contain background to anomalous amounts of gold but the number of samples is probably insufficient to be more than marginally indicative of mineral potential in the area.

Sampling in the Hoey area has revealed strongly anomalous gold and copper values over moderate to narrow widths and distributed from the rim of the canyon to creek level, a vertical separation of about 100 metres. Rocks that host the mineral zones are andesitic to gabbroic in composition and are both sheared and oxidized. Dominant structures trend northerly to

northeasterly and dip steeply to the east. Interpretation of results is speculative due to the difficulties of mapping structures that are disrupted by fractures and to the possible distortions of values that may be introduced by oxidation.

Further work is required to help determine if worthwhile amounts of precious metals are present.

4.0 DISCUSSION OF DATA OBTAINED FROM 1995 WORK

Work in the Hat Project area during 1995 confirmed the presence of strongly altered and fractured bedded rocks in an area that extends from west of Gossan Creek to Big Creek (informal names) on the Hat 3 and 4 claims. Substantial gold and copper values were returned from various samples that were analysed.

It is postulated that at Gossan Creek a high level epithermal system has introduced carbonate and metallic minerals into epiclastic rocks (Stuhini Group). This model implies fracturing and brecciation followed by argillic alteration with development of colloform banding, crustification structures, and cementation of the breccia and introduction of fine grained metallic minerals, including chalcopyrite, pyrite, and tetrahedrite.

At Gossan Creek the wide zone of intense shearing/faulting has been excavated by stream erosion, exposing weakly mineralized bedded rocks, apparently tuffs and arenites. Soil and rock chip sampling indicate that this area may be fitted into the upper level of an hypogene environment. Bonanza type gold deposits often are present at shallow depths below such zones.

The Hoey mineral zone is a complex of gougy fractures developed in mafic volcanic rocks. Specular hematite and fine to coarse grained sulphide minerals are present in fragments of narrow bands that may be either flow top structures or sheared zones. Gangue minerals are only sparcely present, comprising sparry calcite and patchy quartz. Some of the hand-dug trenches did not extend beneath the surface oxidation effects.

Hoey mineralization is characterized by a substantial gold content and the presence of massive, gabbroic host rocks. The controlling fracture system is narrower than that found at Gossan Creek and the rocks do not show evidence of alteration by magmatic hydrothermal fluids. Further exploration should include drilling in search of stronger, less disjointed mineral bands.

ICP - .500 GRAM SAMPLE IS DIGESTED WITH 3ML 3-1-2 HCL-HNO3-H2O AT 95 DEG. C FOR ONE HOUR AND IS DILUTED TO 10 ML WITH WATER.
THIS LEACH IS PARTIAL FOR MN FE SR CA P LA CR MG BA TI B W AND LIMITED FOR NA K AND AL.
ASSAY RECOMMENDED FOR ROCK AND CORE SAMPLES IF CU PB ZN AS > 1%, AG > 30 PPM & AU > 1000 PPB
- SAMPLE TYPE: P1 TO P3 SOIL P4 SS/P5 TF P6 TO P7 ROCK AU* - IGNITED, AQUA-REGIA/MIBK EXTRACT, GF/AA FINISHED.
Samples beginning 'RE' are Reruns and 'RRE' are Reject Reruns.

DATE RECEIVED: AUG 4 1995 **DATE REPORT MAILED:** Aug 12/95 **SIGNED BY:** .....D.TOYE, C.LEONG, J.WANG; CERTIFIED B.C. ASSAYERS

APPENDIX III.

Personnel

1. Erik Ostensoe, P. Geo.

2. Thomas E. Lisle, P. Eng.

Personnel

The following persons carried out the field work described in the accompanying report:

1. Erik A. Ostensoe, P. Geo. - geologist (UBC, 1960)
   - more than thirty years experience in mineral exploration, principally in western North America
   - member of APEGBC, no. 18727
   - performed field work described in this report in period July 9 through July 29, 1995
   - principal author of the report.

2. Thomas E. Lisle, P. Eng. - geologist (UBC, 1964)
   - more than thirty years experience in mineral exploration, principally in western and northern Canada
   - member of APEGBC, Geol. Assoc. Canada, CIMM
   - performed field work described in this report in period July 9 through July 29, 1995.

APPENDIX IV.

Statement of Expenditures

Statement of Expenditures

The following expenditures were incurred in carrying out the work described in the accompanying report: (GST where incurred is included)

	Cost (includes GST)
1. Truck rental - from T. E. Lisle - FWD Ford Bronco - 21 days @ $30/day	$ 674.10
mileage charges - 3590 km @ $0.18	646.20
2. Gasoline -	405.81
3. Telephone calls -	12.15
4. Air Service - flight from Dease Lake to Hatchau Lake

LEGEND

- 5 — Breccia
- 4 — Monzonite - Diorite
- 3 — Andesite, Porphyritic Andesite ± Augite
- 2 — a - fine grained tuff; b - chert
- 1 — Andesite tuff

F — Fault; Q — Quartz veins; C — Carbonate veins; Fractures; Bedding

Mal - malachite; Lim - limonite; Py/Cpy - pyrite/chalcopyrite

(x) Float; Outcrop; shear/shear zone; sil - siliceous
