**REPORT ON DIAMOND DRILLING  
IN THE  
CHATAWAY LAKE AREA  
OF THE  
HIGHLAND VALLEY PROPERTY  
FOR Highbank Resources Ltd.**

**[ASSESSMENT REPORT]**

**INTRODUCTION & TERMS OF REFERENCE**

The present report describes the assessment work that was carried out on the Highland Valley Property (termed “the Property” hereinafter) on behalf of Highbank Resources Ltd., the Optionee. The exploration work described in the report was based on the geological work, conclusions and recommendations contained in earlier reports by the writer (Bergey, 2007; Bergey, 2009; Bergey, 2011.)

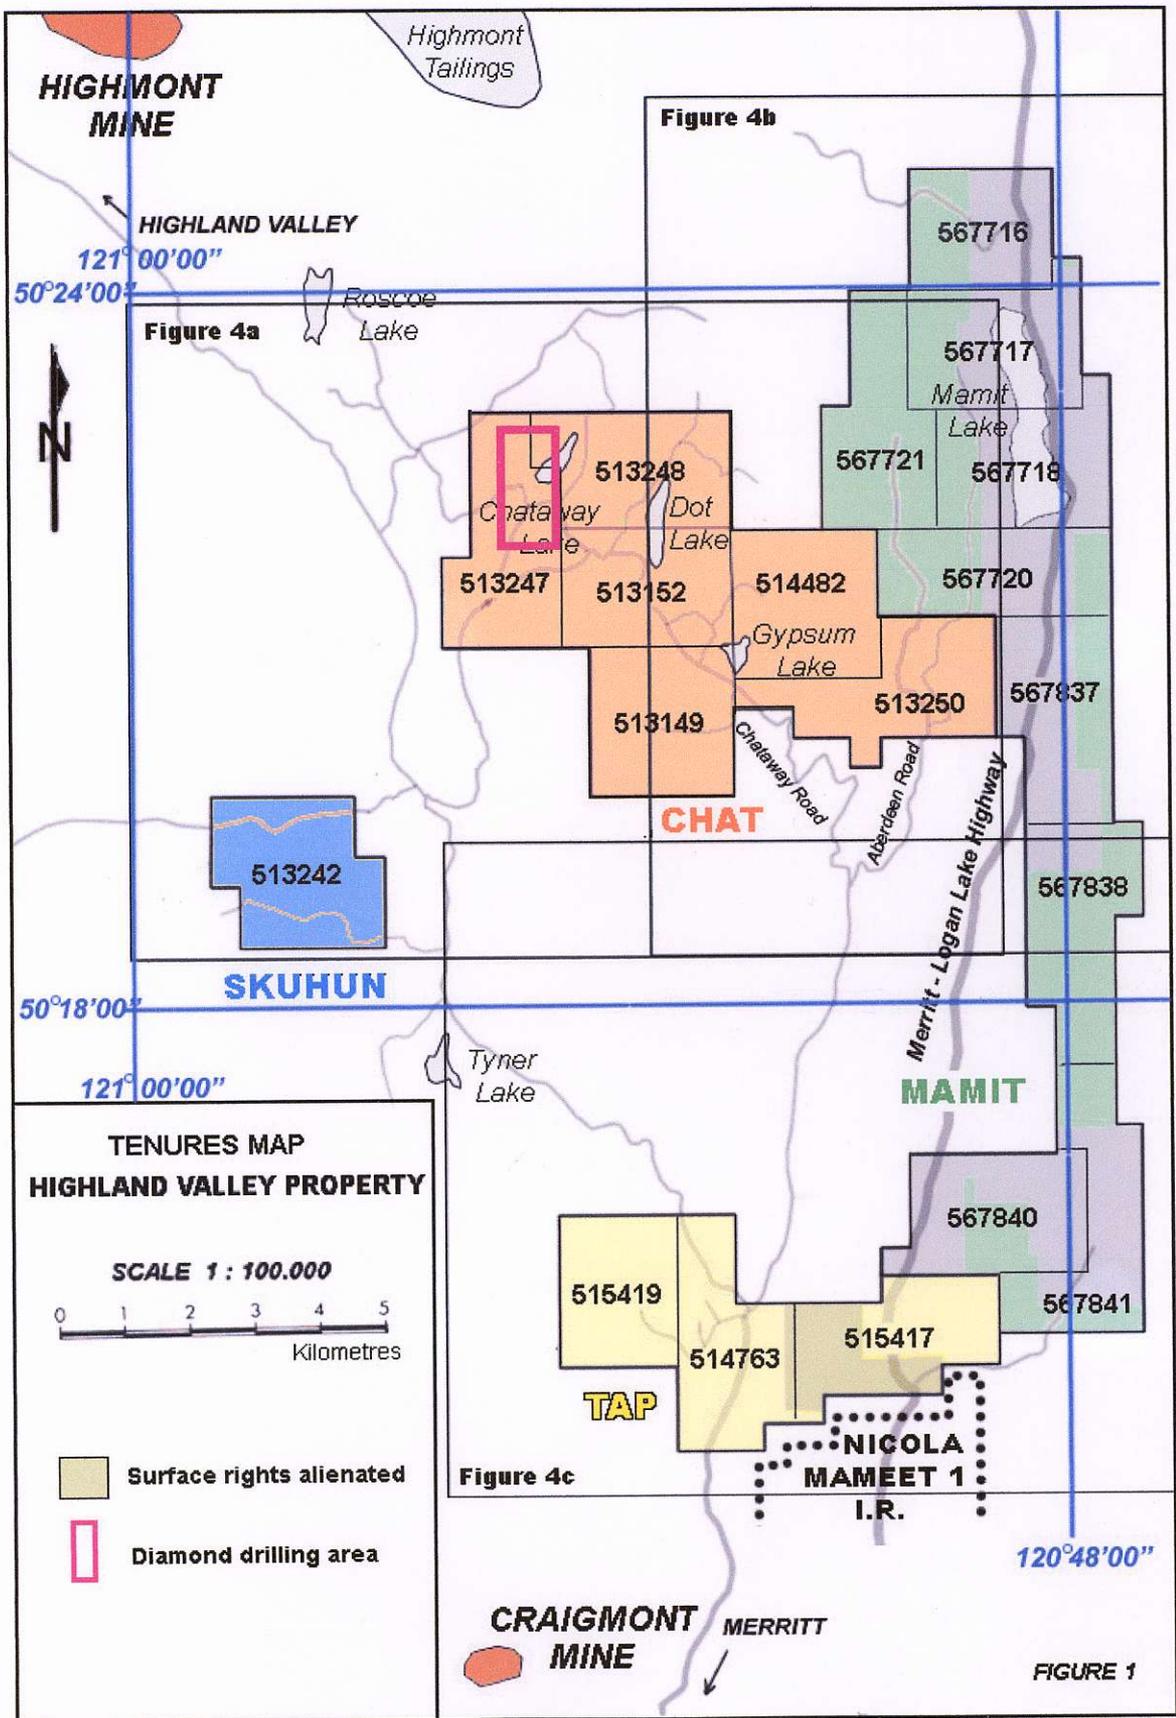

The large Highland Valley Property has been sub-divided into four “blocks” for convenience -- Chat Block, Tap Block, Mamit Block, and the non-contiguous Shuhun Block. The diamond drilling described in the present report was confined to the Chataway Lake Area in the north-western corner of the Chat Block (Figure 1).

**PROPERTY DESCRIPTION**

The Highland Valley Property comprises 18 unpatented Mineral Tenures covering 9418.21 hectares (about 36 square miles) in the Kamloops Mining Division, British Columbia. The tenures are contiguous except for the small Skuhun Block, which lies west of the other blocks.

The locations of the tenures are shown on Figure 1. The National Topographic System designation is 92I36 (Chataway Lake). The centre of the Property is located at Latitude 50°20’N, Longitude 120°53’W.

**Moag Copper Gold Resources Inc.** is the owner of the tenures. **Highbank Resources Ltd.** has an option to acquire a 50% interest in the Property. There is extensive private ownership of land along the valley of Guichon Creek in the eastern portion of the Property. These parcels are shown on Figure 1.

Assessment credit has been claimed for a portion of the expenditures indicated in the present report. Event numbers are: **5091487** & **5091587**.

## LOCATION, ACCESS, CHARACTER OF THE REGION

The Highland Valley Property is located in south-central British Columbia, approximately 200 kilometres northeast of Vancouver, and about 50 kilometres southwest of Kamloops. It is accessible by road from Merritt, located on the Coquihala Highway (Highway 5) south of Merritt (see Figure 2). The route to the drilling area follows Highway 8 west from Merritt to Lower Nicola, thence north on a paved road through the western part of the Tap Block, thence along the all-weather Chataway Lake Road (see Figure 1).

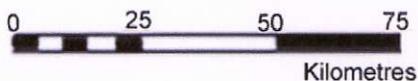

The Property lies mainly atop a high plateau that drops off abruptly toward the Guichon Creek valley to the east. The topography on the plateau is characterized by moderately steep-sided hills with local relief of less than 100 metres except along the western part of the valley of Skuhun Creek, which lies more than 300 metres below the average surface of the plateau. Elevations are highest in the north-western part of the Property, averaging more than 1500 metres in the area surrounding Chataway Lake. Mamit Lake, which occupies a portion of the valley of Guichon Creek, lies below 1000 metres.

The north-western portion of the Property falls within the biogeoclimatic zone classified as *Sub-Boreal Spruce*. To the south and east this is replaced by the *Interior Douglas-Fir* zone. In local terms this means that Lodgepole Pine is supplanted as the predominant tree species by Ponderosa Pine along the more arid lower slopes of the Guichon Creek valley. This transition is apparent in the patchwork of clear-cut logging on the plateau — the result of pine beetle infestation of the favoured Lodgepole Pine.

## GEOLOGICAL SETTING

Chataway Lake is located in the east-central portion of the Guichon Creek batholith, about 10 kilometres southeast of the major mines of the Highland Valley district. Figure 3 illustrates the pattern of the faulting within the eastern portion of the batholith, based on photo-geology.

The Property is located astride the south-eastern margin of the Guichon Creek batholith (Fig. 3). This large igneous intrusion is an elliptical body approximately 60 kilometres north-south by 30 kilometres east-west. It was emplaced into rocks of the Nicola Volcanic Belt in Late Triassic to Early Jurassic time. Several stages of intrusion have been identified, with the oldest intrusive phase located around the periphery and the youngest at the centre of the mass. The following account is based mainly on McMillan (1978) and Casselman et al. (1995).

More than half a century of detailed geological study has resulted in a generally accepted classification of the various phases and phase-varieties of intrusive rocks. Except for the Border Phase, which includes quartz diorite and diorite, most of the rocks in the batholith are mapped as granodiorite, along with lesser amounts of quartz monzonite. Although important variations in chemical composition are apparent in the laboratory, textural differences play the most significant role in distinguishing phases and varieties in the field. In general, the rocks tend to be porphyritic to some extent; the larger phenocrysts are hornblende, biotite and magnetite. Dike rocks related to the younger phases of the batholith are common and these may extend for considerable distances into the older adjoining phases.

The Border Phase is depicted on government geological maps as a nearly continuous girdle around the periphery of the batholith. It is darker in colour than the later intrusive phases and includes a considerable amount of quartz diorite in addition to granodiorite. Rocks that are more mafic in composition, including diorite and gabbro, are present locally along the margin. These rocks are reflected in geophysical surveys as a zone of high magnetic intensity. They are considered by some geologists to be "hybrid" rocks that have consumed quantities of the adjacent Nicola volcanic rock. My recent mapping in the eastern part of the Property suggests that some of the quartz-deficient rocks along the margin of the batholith are part of a younger intrusive phase rather than older hybrid intrusions. The Highland Valley Phase underlies more than half of the exposed area of the Guichon Creek batholith. This phase includes the Guichon variety and the younger Chataway variety as well as various intermediate and more localized varieties. The Guichon variety (along with the Border Phase) underlies the eastern portion of the batholith, including the eastern part of the Chat Block and the western part of the Tap Block. The Chataway variety is present in the central and western parts of the Chat Block. The Chataway Lake drilling area is underlain mainly by rocks of the Chataway Variety adjacent to, and possibly overlapping, the contact with the Bethlehem Phase

The Bethlehem Phase of the intrusive sequence is believed to have been coincident with the earliest period of porphyry copper mineralization in the Highland Valley district (Casselman et al., 1995). [I have not seen any evidence to substantiate this.] The outcrop area is confined mainly to a rather narrow strip east of the Bethesda Phase. However, both field and aeromagnetic evidence suggest that rocks of the Bethlehem phase may be present at depth

beneath a large area that extends to the east across the Chat Group and along the Southeast Belt as defined below.

The Bethsaida Phase was the final major intrusion that formed part of the central core of the Guichon Creek Batholith. The very large copper and copper-molybdenum deposits of the Highland Valley mining district are enclosed within this core and in the adjacent rocks. The Bethsaida Phase terminates a short distance to the north of the major deposits that it encloses. The Skuhun Block and the westernmost part of the Chat Block are located along the margin of the Bethsaida/ Bethlehem core.

Photo-geological interpretation has outlined a number of regional faults within the portion of the Guichon Creek batholith that includes the Property. Most of them were not clearly defined previously. Particularly prominent are a swarm of faults with a general north to north-northeast trend that I refer to as the "north-south regional faults." These faults appear to have been active following the intrusion of all of the major phases of the batholith. The strike of these faults tends to be somewhat sinuous. [The very straight north-south Lornex fault, which offsets the Lornex and Valley Copper segments of the main Highland Valley deposit, is an Eocene feature and not a part of the 'north-south' swarm.] An astonishingly large proportion of significant copper occurrences within the batholith, including all of the major deposits, appear to be associated with regional faults of this orientation. The HVC fault appears to have been offset by the Lornex fault within the main Highland Valley Copper deposit. The Highmont orebody is located astride the Highmont fault. The JA, Bethlehem, Krain and South Seas deposits in turn are located adjacent to a north-south fault that could be the northerly extension of the Highmont fault. The Roscoe Lake fault is occupied by two copper prospects south of the eponymous lake and it extends north to the vicinity of the JA deposit. The former Alwin mine is located adjacent to a north-south fault west of the Valley Copper deposits. The No.4 Zone and the Wiz "mine" south of the Chat Block are associated with south-southwest faults that probably are part of the "north-south" set. Farther to the southeast, Dot Resources Ltd. has recently published a copper resource estimate on several zones that appear to follow "north-south faults". The former Craigmont mine is located in volcanic and sedimentary rocks of the Nicola Group adjacent to the southern margin of the Guichon Creek batholith. A regional "north-south" fault appears to project into mine area, but the immediate vicinity is obscured by younger cover.

Each of the major deposits in the Guichon Creek batholith was emplaced at the junction of one or more interpreted "north-south" faults and an interpreted regional "east-west fault." This special condition does not appear to apply to any of the less significant copper occurrences in the region except for the Alwin Mine.

## REGIONAL MINERALIZATION MODEL

The mines of the Highland Valley copper district, which are located between 8 and 14 kilometres northeast of the Chat Group, are obvious target models. These are the largest producers of copper in Canada, and they generate a substantial tonnage of molybdenum as well. The Highland Valley mines are classified as porphyry copper and copper-molybdenum deposits of the calc-alkaline type. They include several very large orebodies (150 million to more than one billion tonnes) that are spatially associated with regional faults, but that are not obviously aligned along faults except for the unmined JA deposit, which is elongated parallel to the "east-west" Highland Valley fault zone, possibly due to later fault offsets. Almost all of the mineralization occurs along fractures -- and fracture density is the most important factor influencing ore grade (Casselman et al. (1995). North-south and east-west fracturing appears to be dominant (Highland Valley Copper mine staff, pers. comm.) The copper minerals are bornite and chalcopyrite. Pyrite is present, but it is not abundant in the ore. The average ore grade depends to some extent on copper price but historically fell within the range of 0.30 to 0.45%. The total sulphide content of an orebody may be less than 2%. The mineralized zones are not enriched in magnetite. Consequently, geophysical techniques other than induced polarization (IP) are ineffective, and even the IP response over a major deposit may be relatively weak, particularly if molybdenum is a co-product. This problem is exacerbated on the plateau surrounding Chataway Lake, where deep oxidation beneath an ancient land surface has resulted in a drastic reduction of the metallic-mineral content of the near-surface rocks.

The major copper deposits of the Highland Valley area are found mainly within the Bethsaida and Bethlehem phases of the Guichon Creek batholith. However, ore-grade mineralization extends into the adjacent, somewhat older, intrusive rocks, particularly in association with high-level dikes and intrusive breccia. This is not to say that the remainder of the batholith lacks widespread indications of copper mineralization. "Vein-type" deposits have been explored and mined on a very small scale for more than a century within an area southeast of the property. (These are more properly referred to as shear-related deposits). Most of them occur along or adjacent to north- to north-northwest-trending regional faults.

As noted above, the photo-geological interpretation outlined a number of very continuous faults within the Guichon Creek batholith that I have termed "north-south regional faults." An astonishingly large proportion of the known mineral occurrences in the region, including all of the major mines and the smaller Alwin, Krain, South Seas, Yubet and Dot deposits, appear to be spatially associated with these structures. The recent copper discovery by Happy Creek Minerals west of Chataway Lake has a linear north-south orientation. It appears to be related to a cluster of minor faults located east of and parallel to the Roscoe Lake fault.

It is evident that an individual north-south regional fault zone by itself is unlikely to provide the “stockwork” fracturing that is the hallmark of the Highland Valley deposits. This requirement could be fulfilled either by cross faulting or by stresses associated to high-level intrusions and intrusive breccias. Regional east-west faults have been interpreted to intersect all of the major copper deposits.

[A well defined linear feature that follows the valley occupied by Chataway Creek & Chataway Lake is interpreted to reflect a regional northwest-trending fault. This structure was a major factor in the planning of the diamond drilling program, since deep overburden across the broad valley inhibited previous exploration. The age of the “Chataway Creek” fault is unknown. However, the possibility that the structure might have provided pre-ore fracturing was too vital to ignore.]

## **DIAMOND DRILLING**

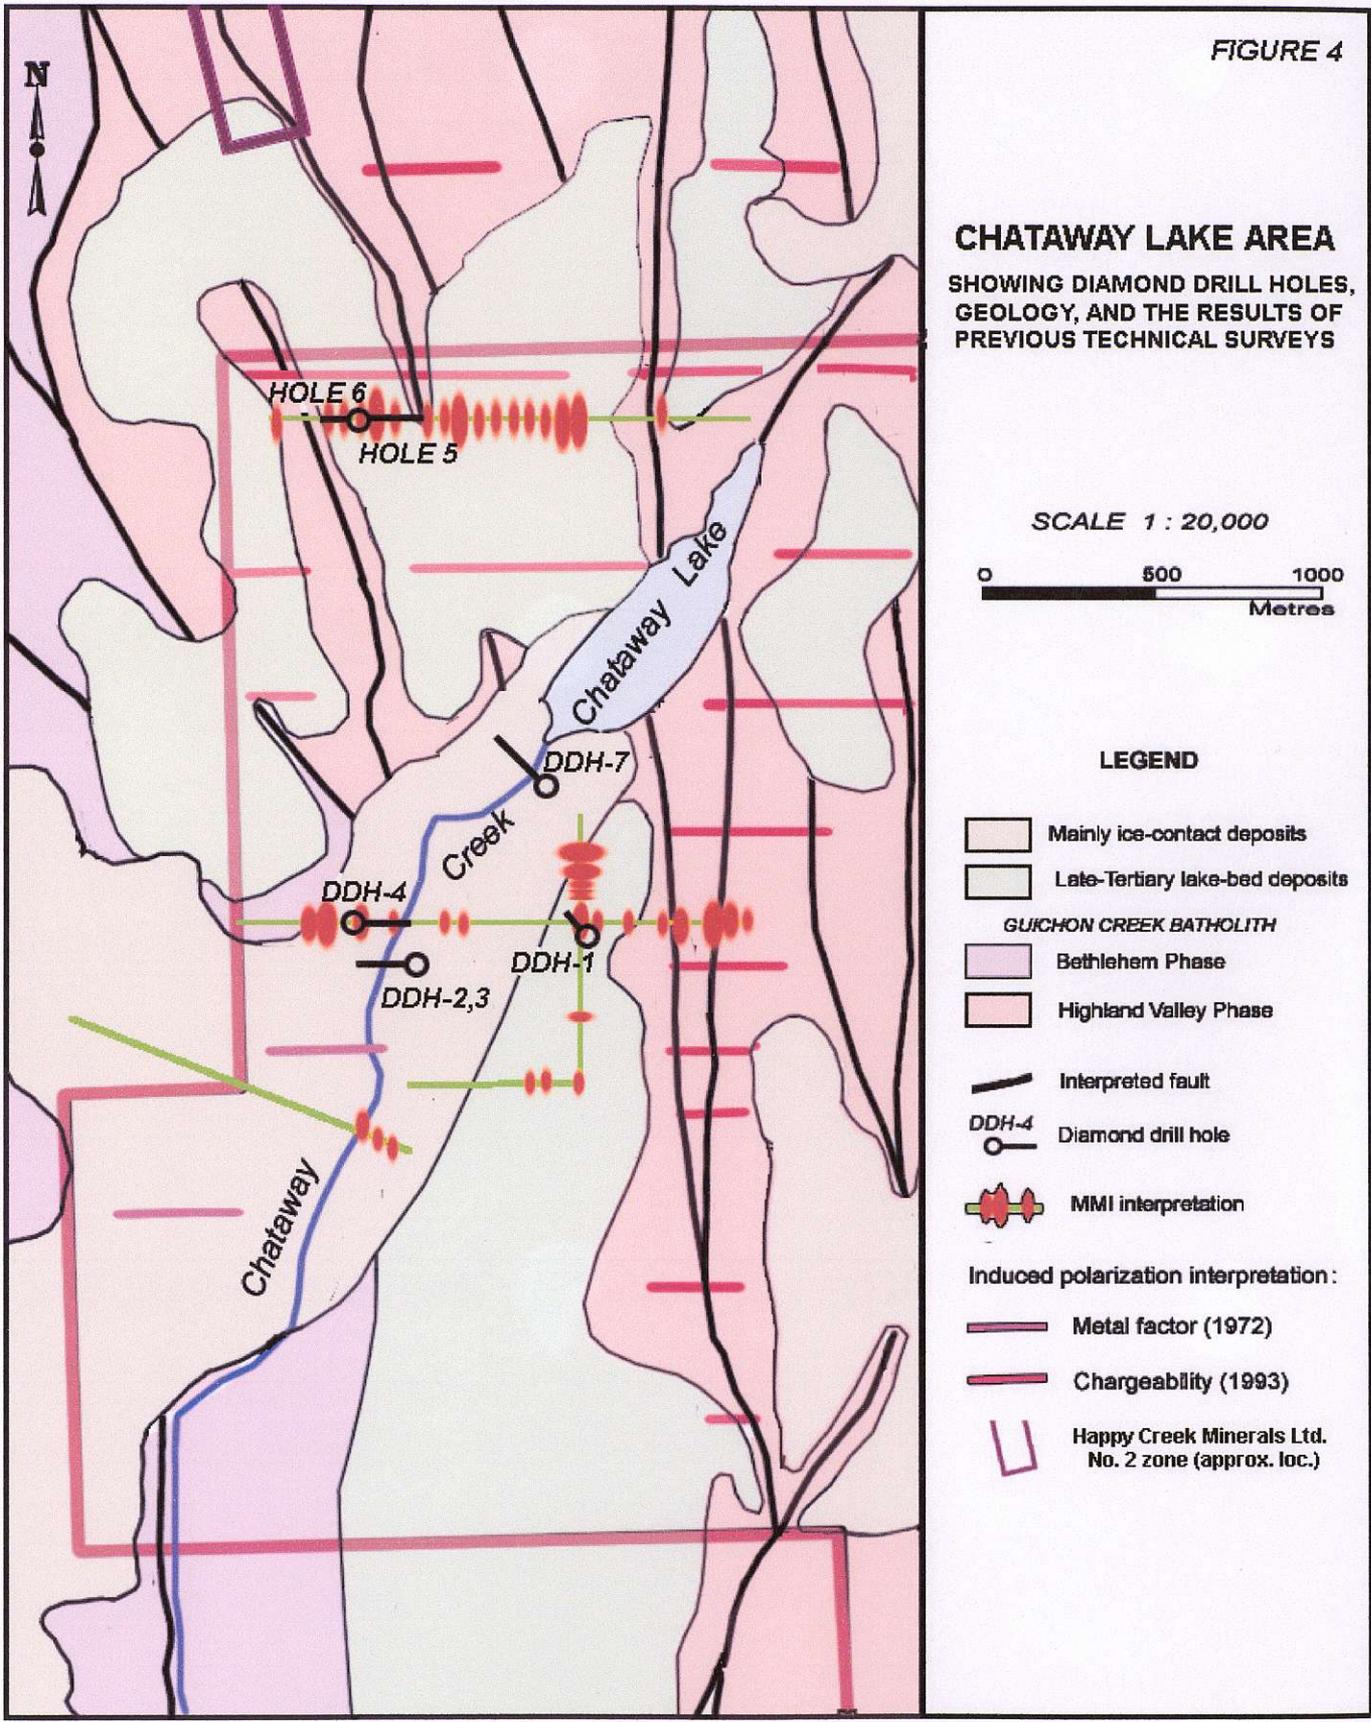

### **BACKGROUND**

The 2011 diamond drilling program was based mainly on the recent exploration work carried out by the co-owners of the Property. This work is described in Assessment Reports (Bergey, 2007; Bergey, 2009; Bergey, 2011). Figure 4 shows the location of the seven diamond drill holes in relation to the geology of the Chataway Lake Area and the geochemical and geophysical surveys.

Remnants of a thin sedimentary unit of probable late Tertiary age surround the lake, and Late-glacial melt-out deposits underlie the Chataway Creek valley and its surroundings. As a result, the bedrock to the area west and southwest of Chataway Lake is covered almost entirely by transported cover material. The overburden is particularly thick along the valley southwest of Chataway Lake. Several previous drill holes failed to reach bedrock at depths of up to 100 metres. The nearly continuous transported cover has severely impacted on geological and geochemical prospecting and on soil geochemical sampling.

The Mobile Metal Ion (MMI) geochemical technique was utilized as a means of detecting mineralization beneath the overburden. The MMI technique has been proven to be useful in this regard, but it is difficult to interpret and its depth limitations in the British Columbia are poorly understood. Samples were collected by Highbank Resources along widely spaced lines in several parts of the Highland Valley Property, including the Chataway Lake Area, as a test of the effectiveness of the method.

FIGURE 4

Extensive Induced Polarization (IP) surveys have been carried out in the map area. The anomalous indications shown on Figure 4 were taken from Hallof & Mullan (1972), and Walcott (1993).

Seven diamond drill holes were completed in the 2011 program, for a total length of 1548 metres. The drilling was supervised by the author. Core logging and the selection of samples for assay were carried out by Brian Callaghan. The samples were assayed by Agat Laboratories, using an Aqua Regia Digestion – Metals Package, ICP-OES finish.

## **DISCUSSION OF THE DRILLING RESULTS**

### DDH 11-1

In the mid-1960's, electromagnetic and shallow IP surveys indicated interesting anomalous zones south of Chataway Lake. Subsequent drilling was carried out by Chataway Exploration. A news release in the George Cross News Letter of February 8, 1967 (quoted in Troup, 1992) stated that copper mineralization had been intersected in 4 diamond drill holes and gave an inferred resource of 544,320 tonnes grading 1.58% copper. Since no follow-up to these results has been recorded, it can be inferred that the quoted results were tainted. However, the MMI test line in the vicinity was positive and it was considered possible that the lack of follow-up was due to the absence of conventional soil geochemical indications because of the transported overburden that covers the entire prospect area.

The drilling site has been logged but we were able to identify the old roads and several drill sites. DDH 11-1 was drilled through the centre of the group of putatively mineralized holes. No significant mineralization was encountered. However, about half of the samples showed elevated copper values. The drill log indicated that there was scattered, weak mineralization in weakly altered granodiorite.

### DDH 11-2

The distinct linear feature defined by Chataway Lake and Chataway Creek was interpreted to reflect a northeast-trending regional fault. This interpretation was supported by the indication of a strong resistivity anomaly in the 1993 IP survey. A wide area along the interpreted fault zone is covered by thick overburden – and this area had not been tested by drilling except along the margins.

DDH was collared a short distance east of Chataway Creek, and was drilled due west. The hole intersected fractured and altered granodiorite at a depth 123 metres. The hole was abandoned when the casing twisted off during reaming of the fractured bedrock.

### DDH 11-3

This hole was drilled at a steeper angle from the same site as the previous one. The rock was highly fractured, but no significant mineralization was noted in the logs or in the core assays.

### DDH 11-4

Since the dip of the interpreted Chataway Creek fault was unknown, this hole was drilled from west to east at a site about 100 metres north and 200 metres west of DDH 11-3 in case DDH 11-3 missed the zone because of a west dip. The results were very similar to those in the previous hole. No significant mineralization was indicated. However, there were numerous fractured and altered sections, some with elevated copper values.

### DDH 11-5

The hole was drilled to the east to test an interpreted north-south fault within a wide zone of anomalous MMI indications. The anomaly was located along the apparent projection of the No.2 Zone, which was discovered by Happy Creek Minerals Ltd. about a kilometre to the north-northwest. Sections of potassic and argillic alteration were more numerous than in previous drill holes and elevated copper values also were more common. The only significant assay was 0.25% copper over 2.0 metres.

### DDH 11-6

The hole was drilled toward the west from the same site as the previous one in order to test the western part of the same target. This hole intersected the best mineralization encountered in the drill program. The best section averaged 0.12% copper over 15 metres. A 2-metre section deeper in the drill hole averaged 0.65% copper over 2 metres. Silver correlates strongly with copper, but there are no correlations with other metals.

The strongest mineralization was noted within zones of alteration (argillic, potassic), shearing, and fracturing. Chalcocite occurs along slips and pyrite appears to be rare, indicating that oxidation of sulphides occurs to a depth of at least 100 metres. This oxidation is typical of the Chataway Lake area, as mentioned earlier. The late Tertiary(?) erosion surface is located at the base of the "overburden" at a depth of about 20 metres in the drill hole.

### DDH 11-7

The hole was located close to the southern tip of Chataway Lake and was drilled toward the northwest. It was intended to test the interpreted Chataway Creek fault within an extremely low resistivity anomaly. Assays are all very low (background levels) except for a 2-metre section of 0.21% copper.

**FIGURE 8**

## CONCLUSIONS

1. The three diamond drill holes that were intended to investigate the previously untested Chataway Creek fault zone were almost completely barren of copper mineralization. There was little evidence of intense deformation or "gouge" to indicate discrete faults. However, fairly intense open fracturing is abundant in the core and this presumably accounts for the topographic and geophysical expression of a regional structural zone. It is possible that a more distinct fault lies west of the drilling area. In any event, the lack of mineralization suggests that the northeast-trending "Chataway Creek Zone" is a post-ore structure.
2. The significant mineralization encountered in DDH 11-6 is associated with more distinct evidence of faulting – fault gouge and slickensides. This mineralization appears to be located on the southward extension of a mineralized zone previously identified on the adjoining property. The zone follows a fault that was previously interpreted by photo-geology. There is considerable evidence that north-south faults may have acted as conduits for hydrothermal fluids. However, wider zones of mineralization appear to be associated with lesser parallel structures. These can be identified on the air photos only under exceptional circumstances – e.g., in recent clear-cuts.
3. The "Chataway Zone" test south of Chataway Lake failed to identify significant copper mineralization, although elevated copper values were indicated in the core. The reported mineral resource almost certainly was a fabrication, deliberate or otherwise.
4. The results of the drilling support the usefulness of the MMI technique under a relatively shallow cover (at least 20 metres) of porous material. Since no deeper mineralization was intersected in the recent drilling, its effectiveness at much greater depths is uncertain.

## RECOMMENDATIONS

The mineralized zone encountered in DDH 11-6 should be tested by drilling along the projection of the zone to the south. A similar zone of interest, located a short distance east of the drilling area, is manifested by chargeability & MMI anomalies follows an interpreted north-south regional fault for three kilometres within the Property. Drilling is recommended for this zone as well. Detailed recommendations will be proposed in conjunction with proposals for the testing of drilling targets that have been identified elsewhere on the large Highland Valley Property.

## STATEMENT OF COSTS

## **CERTIFICATE OF AUTHOR**

**I, William Richard Bergey, P.Eng., do hereby certify that:**

1. I am a Consulting Geologist with an office at 25789-8th Avenue, Aldergrove , B.C., Canada V4W 2J8.
2. I graduated with an Honours Bachelor of Arts degree from McMaster University in 1947. I later attended graduate school at the University of Toronto (Department of Geology), and at Colorado School of Mines (Department of Geophysics).
3. I am a member of the Association of Professional Engineers, Geologists and Geophysicists of the Province of British Columbia, and I am a Senior Fellow of the Geological Society of America.
4. I have worked as a geologist in most aspects of mineral exploration for the past 64 years.

---

W.R.Bergey, P.Eng.

Summary

Hole 5 was drilled to the east and located south west of Chataway Lake in the southwest corner of the claim block to intersect a northsouth interpreted fault zone. This hole was collared in less overburden cover and bedrock was reached at 24.38m. Malachite chalcocite traces of bornite and native copper are associated with multiple 30-50-70 deg fractures in kspar envelopes overprinted by wk to mod argillic alteration in occasional blocky core from 31.00m-53.00m, 70.00m-92.00m, 160.00m-198.00m, 231.00-234.60m
